PREFACE TO THE SEVENTH EDITION.

The outstanding feature of the interval that has elapsed since the sixth edition of this work appeared is the impetus given to bacteriological research by the urgent requirements of practical medicine and surgery in the war. The success which has attended the efforts put forth is shown in the additions we have made to the chapters dealing with cerebro-spinal fever, with intestinal infections,—both bacterial and protozoal,—with tetanus, and with the grave conditions occurring in wounds. It is manifest likewise in the inclusion of new sections on infective jaundice and also on trench fever, which observations in both the field and the laboratory have differentiated from allied affections. Apart from aspects of bacteriology brought into prominence through the war, the whole book has been thoroughly revised, a number of new methods have been described, and new illustrations have been added.

October 1918.

PREFACE TO THE FIRST EDITION.

THE science of Bacteriology has, within recent years, become so extensive, that in treating the subject in a book of this size we are necessarily restricted to some special departments, unless the description is to be of a superficial character. Accordingly, as this work is intended primarily for students and practitioners of medicine, only those bacteria which are associated with disease in the human subject have been considered. We have made it a chief endeavour to render the work of practical utility for beginners, and, in the account of the more important methods, have given elementary details which our experience in the practical teaching of the subject has shown to be necessary.

In the systematic description of the various bacteria, an attempt has been made to bring into prominence the evidence of their having an etiological relationship to the corresponding diseases, to point out the general laws governing their action as producers of disease, and to consider the effects in particular instances of various modifying circumstances. Much research on certain subjects is so recent that conclusions on many points must necessarily be of a tentative character. We have, therefore, in our statement of results aimed at drawing a distinction between what is proved and what is only probable.

In an Appendix we have treated of four diseases; in two of these the causal organism is not a bacterium, whilst in the other two its nature is not yet determined. These diseases have been

included on account of their own importance and that of the pathological processes which they illustrate.

Our best thanks are due to Professor Greenfield for his kind advice in connection with certain parts of the work. We have also great pleasure in acknowledging our indebtedness to Dr. Patrick Manson, who kindly lent us the negatives or preparations from which Figs. 174–179 have been executed.

As we are convinced that to any one engaged in practical study, photographs and photomicrographs supply the most useful and exact information, we have used these almost exclusively in illustration of the systematic description. These have been executed in the Pathological Laboratory of the University of Edinburgh by Mr. Richard Muir. The line drawings were prepared for us by Mr. Alfred Robinson, of the University Museum, Oxford.

To the volume is appended a short Bibliography, which, while having no pretension to completeness, will, we hope, be of use in putting those who desire further information on the track of the principal papers which have been published on each of the subjects considered.

FIG. 21. THE PARASITE OF MILD TERTIAN MALARIA.

Cycle I. (Schizogony). Asexual cycle in the human blood.

a. Sporozoite entering red blood corpuscle and forming young trophozoite.
b. Young trophozoite in red blood corpuscle.
c. Young trophozoite in red blood corpuscle, with accumulation of pigment.
d. Large pigmented trophozoite.
e. Mature schizont.
f. Commencing segmentation of schizont.
g. Further stage of segmentation.
h. Segmented schizont; formation of merozoites.
i. Disintegration of red blood corpuscle, setting free the merozoites.
j. Young merozoite entering red blood corpuscle.
k. Macrogametocyte, or female sporont.
l. Microgametocyte, or male sporont.

Cycle II. (Sporogony). Sexual cycle in the mosquito.

In the cavity of the stomach of the mosquito:
m. Microgametocyte.
n. Macrogametocyte.
o. Formation of microgametes from the microgametocyte.
p. Free microgamete.
q. Microgamete entering the macrogamete.
r. Zygote or ookinete.

s. Sporocyst.
t. Formation of sporoblasts in the sporocyst.
u. Formation of sporozoites from sporoblasts.
v. Rupture of sporocyst, setting free the sporozoites.
w. Free sporozoites in the body fluid.
x. Accumulation of sporozoites in the salivary gland.
y. Sporozoites passing from gland duct into the blood of man.

FIG. 22. THE PARASITE OF MALIGNANT MALARIA.

a. Young trophozoite entering red blood corpuscle.
b. Do. in red corpuscle.
c. Multiple infection of red corpuscle.
c'. Multiple infection with chromatic stippling in cellular protoplasm; a similar cell is seen lying beneath *a*,—it contains a pigmented trophozoite.
d. Pigmented trophozoite.
e. Segmented schizont, cluster of merozoites.
f. Microgametocyte, "male crescent."
g. Macrogametocyte, "female crescent."
h. Red blood corpuscle with chromatic stippling.
i. Large mono-nucleated phagocyte containing malarial pigment.

MANUAL OF BACTERIOLOGY

CHAPTER I.

GENERAL MORPHOLOGY AND BIOLOGY.

Introductory.—At the bottom of the scale of living things there exists a group of organisms to which the name of bacteria is usually applied. These are apparently of very simple structure, and may be subdivided into two sub-groups, a lower and simpler and a higher and better-developed.

The *lower forms* are the more numerous, and consist of minute unicellular masses of protoplasm devoid of chlorophyll, which multiply by simple fission. Some are motile, others non-motile. Their minuteness may be judged of by the fact that in one direction at least they usually do not measure more than ·1 μ ($\frac{1}{25000}$ inch). These forms can be classified according to their shapes into three main groups—(1) A group in which the shape is globular. The members of this are called *cocci*. (2) A group in which the shape is that of a straight rod—the proportion of the length to the breadth of the rod varying greatly among the different members. These are called *bacilli*. (3) A group in which the shape is that of a curved or spiral rod. These are called *spirilla*. The full description of the characters of these groups will be more conveniently taken later (p. 12). In some cases, especially among the bacilli, there may occur under certain circumstances changes in the protoplasm whereby a resting stage or spore is formed.

The *higher forms* show advance on the lower along two lines. (1) On the one hand, they consist of filaments made up of simple elements such as occur in the lower forms. These filaments may be more or less septate, may be provided with a

sheath, and may show branching either true or false. The minute structure of the elements comprising these filaments is analogous to that of the lower forms. Their size, however, is often somewhat greater. The lower forms sometimes occur in filaments, but here every member of the filament is independent, while in the higher forms there seems to be a certain interdependence among the individual elements. For instance, growth may occur only at one end of a filament, the other forming an attachment to some fixed object. (2) The higher forms, moreover, present this further development, that in certain cases some of the elements may be set apart for the reproduction of new individuals.

Terminology.—The term bacterium of course in strictness only refers to the rod-shaped varieties of the group, but as it has given the name bacteriology to the science which deals with the whole group, it is convenient to apply it to all the members of the latter, and to reserve the term bacillus for the rod-shaped varieties. Other general words, such as germ, microbe, micro-organism, are used as synonymous with bacterium, though these are often made to include minute organisms belonging to other groups.

While no formed living organisms lower than the bacteria are known (though, as will be seen later, the existence of life associated with matter in an ultra-microscopic state is probable), the upper limits of the group are difficult to define, and it is impossible at present to give other than a provisional classification of the forms which all recognise to be bacteria. The division into lower and higher forms, however, is fairly well marked, and we shall therefore refer to the former as the lower bacteria, and to the latter as the higher bacteria.

Morphological Relations.—The relations of the bacteria to the animal kingdom on the one hand and to the vegetable on the other constitute a difficult question. It is best to think of there being a group of small, unicellular organisms, which may be survivals of the most primitive forms of life before differentiation into animal and vegetable types had occurred and before in an individual cell nucleus had been differentiated from cytoplasm. This would include the flagellata and infusoria, the myxomycetes, the lower algæ, and the bacteria. To the lower algæ the bacteria show many similarities. These algæ are unicellular masses of protoplasm, having generally the same shapes as the bacteria, and largely multiplying by fission. Endogenous sporulation, however, does not occur, nor is motility necessarily associated with the possession of flagella. Also their protoplasm differs from that of the bacteria in containing chlorophyll and another blue-green pigment called phycocyan. From the morphological resemblances between these algæ and the bacteria, and from the fact that fission plays a predominant part in the multiplication of both, they

were formerly grouped together in one class as the Schizophyta or splitting plants. And of the two divisions forming these Schizophyta the splitting algæ were denominated the schizophyceæ, while the bacteria or splitting fungi were called the schizomycetes. The bacteria were, therefore, often spoken of as the schizomycetes. This classification in its reference to splitting fungi reflects the view, now practically abandoned, that the bacteria represent the last stage of a progressive degeneration which parasitism has entailed in the fungoid plants.

General Morphology of the Bacteria.

The Structure of the Bacterial Cell.—When examined under the microscope, in their natural condition, *e.g.*, in water, bacteria appear merely as colourless refractile bodies of the different shapes named. Spore formation and motility, when these exist, can also be observed, but little else can be made out. For their proper investigation advantage is always taken of their affinities for various dyes, especially those which are usually chosen as good stains for the nuclei of animal cells. Certain points have thus been determined. The bacterial cell consists of a sharply contoured mass of protoplasm which reacts to, especially basic, aniline dyes like the nucleus of an animal cell. A healthy bacterium when thus stained presents the appearance of a finely granular or almost homogeneous structure. The protoplasm is surrounded by an envelope which can in some cases be demonstrated by overstaining a specimen with a strong aniline dye, when it will appear as a halo round the bacterium. This envelope may sometimes be seen to be of considerable thickness. Its innermost layer is probably of a denser consistence, and sharply contours the contained protoplasm, giving the latter the appearance of being surrounded by a membrane. It is only, however, in some of the higher forms that a definite membrane occurs. Sometimes the outer margin of the envelope is sharply defined, in which case the bacterium appears to have a distinct capsule, and is known as a capsulated bacterium (*vide* Fig. 1, *h*; and Fig. 58). The cohesion of bacteria into masses depends largely on the character of the envelope. If the latter is glutinous, then a large mass of the same species may occur, formed of individual bacteria embedded in what appears to be a mass of jelly. When this occurs, it is known as a *zooglœa* mass. On the other hand, if the envelope has not this cohesive property the separation of individuals may easily take place, especially in a fluid medium in which they may float entirely free from one another. Many of the higher bacteria possess a sheath which has a much more definite structure than is found

among the lower forms. It resists external influences, possesses elasticity, and serves to bind the elements of the organism together.

Reproduction among the Lower Bacteria.—When a bacterial cell is placed in favourable surroundings, it multiplies,—usually by simple fission. In the process a constriction appears in the middle and a transverse unstained line develops across the protoplasm at that point. The process goes on till two individuals can be recognised, which may remain for a time attached to one another, or become separate, according to the character of the envelope, as already explained. In most bacteria growth and multiplication go on with great rapidity. A bacterium may reach maturity and divide in from twenty minutes to half an hour. If division takes place only every hour, from one individual after twenty-four hours 17,000,000 similar individuals will be produced. As shown by the results of artificial cultivation, others, such as the tubercle bacillus, multiply much more slowly. In some cases the bacterial cell enlarges before division, in others the cell divides and each element then expands to its adult size. If, in the latter alternative, multiplication is proceeding rapidly, great variation in the size of the individuals may be observed, and this may give rise to anomalous appearances.

From investigations by Graham-Smith and others, it appears that the consistence of the envelope may have an importance in modifying the naked-eye and low-power appearances presented by bacterial colonies which constitute a feature in the identification of species (see p. 134). Graham-Smith, working with bacilli, differentiates four groups—a "loop-forming," in which the envelope is so tough that, after division, rupture but rarely occurs (b. anthracis); a "folding" group, in which the envelope is so flexible and extensile that the members of a chain can be folded on one another as successive divisions take place (b. pestis); a "snapping" group, in which partial rupture of the envelope occurs on division (b. diphtheriæ); and a "slipping" group, where the envelope readily breaks, and successively developed bacilli slip past each other (v. choleræ).

When bacteria are placed in unfavourable conditions as regards food, etc., growth and multiplication take place with difficulty. In the great majority of cases this is evidenced by changes in the appearances of the protoplasm. Instead of its maintaining the regularity of shape seen in healthy bacteria, various aberrant appearances are presented. This occurs especially in the rod-shaped varieties, where flask-shaped or dumb-bell-shaped individuals may be seen. The regularity in structure and size is quite lost. The appearance of the protoplasm also is often altered. Instead of, as formerly, staining well, it

does not stain readily, and may have a uniformly pale homogeneous appearance, while in an old culture only a small proportion of the bacteria may stain at all. Sometimes, on the other hand, a degenerated bacterium contains intensely stained granules or globules which may be of large size. Such aberrant and degenerate appearances are referred to as *involution forms* (Fig. 1, i^1, i^2). That these forms really betoken degenerate changes is shown by the fact that, on their being again transferred to favourable conditions, only slight growth at first takes place. Many individuals have undoubtedly died, and the remainder which live and develop into typical forms may sometimes have lost some of their properties.

Reproduction among the Higher Bacteria.—Most of the higher bacteria consist of thread-like structures more or less septate and often surrounded by a sheath. The organism is frequently attached at one end to some object or to another individual. It grows to a certain length and then at the free end certain cells, called gonidia, are cast off from which new individuals are formed. These gonidia may be formed by a division taking place in the terminal element of the filament such as has occurred in the growth of the latter. In some cases, however, division takes place in three dimensions of space. The gonidia have a free existence for a certain time before becoming attached, and in this stage are sometimes motile. They are usually rod-like in shape, sometimes pyriform. They do not possess any special powers of resistance.

Spore Formation.—In certain species of the lower bacteria, under certain circumstances, changes take place in the protoplasm which result in the formation of bodies called spores, to which the vital activities of the original bacteria are transferred. Spore formation occurs chiefly among the bacilli and in some spirilla. Its commencement in a bacterium is indicated by the appearance in the protoplasm of a minute highly refractile granule unstained by the ordinary methods. This increases in size, and assumes a round, oval, or short rod-shaped form, always shorter but often broader than the original bacterium. In the process of spore formation the rest of the bacterial protoplasm may remain unchanged in appearance and staining power for a considerable time (*e.g.*, b. tetani), or, on the other hand, it may soon lose its power of staining and ultimately disappear, leaving the spore in the remains of the envelope (*e.g.*, b. anthracis). This method of spore formation is called *endogenous*. Bacterial spores are always non-motile. The spore may appear in the centre of the bacterium, or it may be at one extremity, or a short distance from one extremity (Fig. 1, *s*). In structure the spore consists of a mass of protoplasm surrounded by a dense membrane. This can be demonstrated by methods which will

be described, the underlying principle of which is the prolonged application of a powerful stain. The membrane is supposed to confer on the spore its characteristic feature, namely, great capacity of resistance to external influences such as heat or noxious chemicals. Koch, for instance, in one series of experiments, found that while the bacillus anthracis in the unspored form was killed by a two minutes' exposure to 1 per cent. carbolic acid, spores of the same organism resisted an exposure of from one to fifteen days.

When a spore is placed in suitable surroundings for growth, it again assumes the original bacillary or spiral form. The capsule may dehisce either longitudinally, or terminally, or transversely. In the last case the dehiscence may be partial, and the new individual may remain for a time attached by its ends to the hinged spore-case, or the dehiscence may be complete and the bacillus grow with a cap at each end consisting of half the spore-case. Sometimes the spore-case does not dehisce, but is simply absorbed by the developing bacterium.

It is important to note that, in the bacteria, spore formation is rarely, if ever, to be considered as a method of multiplication. In at least the great majority of cases only one spore is formed from one bacterium, and only one bacterium in the first instance from one spore. Sporulation is to be looked upon as a *resting stage* of a bacterium, and is to be contrasted with the stage when active multiplication takes place. The latter is usually referred to as the *vegetative stage* of the bacterium. Regarding the signification of spore formation in bacteria, there has been some difference of opinion. According to one view, it may be regarded as representing the highest stage in the vital activity of a bacterium. There is thus an alternation between the vegetative and spore stage, the occurrence of the latter being necessary to the maintenance of the species in its greatest vitality. Such a rejuvenescence, as it were, through sporulation, is known in many algæ. In support of this view there are certain facts. In many cases, for instance, spore formation only occurs at temperatures specially favourable for growth and multiplication. There is often a temperature below which, while vegetative growth still takes place, sporulation will not occur; and in the case of b. anthracis, if the organism be kept at a temperature above the limit at which it grows best, not only are no spores formed, but the strain may lose the power of sporulation. Furthermore, in the case of bacteria preferring the presence of oxygen for their growth, an abundant supply of this gas may favour sporulation. It is probable that even

among bacteria preferring the absence of oxygen for vegetative growth, the presence of this gas favours sporulation. Some facts relating to the cases in which two spores are formed in one bacterium have been adduced to support the view that sporulation may represent a degenerate sexual process. Here a partial fission of a cell has been observed, followed by a re-fusion of the protoplasmic moieties and the formation of a spore at each end of the rod. The second view with regard to sporulation is that a bacterium only forms a spore when its surroundings, especially its food supply, become unfavourable for vegetable growth; it then remains in this condition until it is placed in more suitable surroundings. Such an occurrence would be analogous to what takes place under similar conditions in many of the protozoa. Often sporulation can be prevented from taking place for an indefinite time if a bacterium is constantly supplied with fresh food (the other conditions of life being equal). The presence of substances excreted by the bacteria themselves plays, however, a more important part in making the surroundings unfavourable than the mere exhaustion of the food supply. A living spore will always develop into a vegetative form if placed in a fresh food supply. With regard to the rapid formation of spores when the conditions are favourable for vegetative growth, it must be borne in mind that in such circumstances the conditions may really very quickly become unfavourable for a continuance of growth, since not only will the food supply around the growing bacteria be rapidly exhausted, but the excretion of effete and inimical matters will be all the more rapid.

We must note that the usually applied tests of a body developed within a bacterium being a spore are (1) its staining reaction, namely, resistance to ordinary staining fluids, but capacity of being stained by the special methods devised for the purpose (*vide* p. 106); (2) the fact that the bacterium containing the spore has higher powers of resistance against inimical conditions than a vegetative form. It is important to bear these tests in mind, as, in some of the smaller bacteria especially, it is very difficult to say whether they spore or not. There may appear in such organisms small unstained spots, the significance of which is very difficult to determine.

The Question of Arthrosporous Bacteria.—It is stated by Hueppe that among certain organisms, *e.g.*, some streptococci, certain individuals may, without endogenous sporulation, take on a resting stage. These become swollen, stain well with ordinary stains, and they are stated to have higher power of resistance than the other forms; further, when vegetative

life again occurs, it is from them that multiplication is said to take place. From the fact that there is no new formation within the protoplasm, but that it is the whole of the latter which participates in the change, these individuals have been called *arthrospores*. The existence of such special individuals amongst the lower bacteria is extremely problematical. They have no distinct capsule, and they present no special staining reactions, nor any microscopic features by which they can be certainly recognised, while their alleged increased powers of resistance are very doubtful. All the phenomena noted can be explained by the undoubted fact that in an ordinary growth there is very great variation among the individual organisms in their powers of resistance to external conditions.

Motility.—As has been stated, many bacteria are motile. Motility can be studied by means of hanging-drop preparations (*vide* p. 69). The movements are of a darting, rolling, or vibratile character. The degree of motility depends on the species, the temperature, the age of the growth, and on the medium in which the bacteria are growing. Sometimes the movements are most active just after the cell has multiplied, sometimes it goes on all through the life of the bacterium, sometimes it ceases when sporulation is about to occur. Motility is associated with the possession of fine wavy thread-like appendages called flagella, which for their demonstration require the application of special staining methods (*vide* Fig. 1, *q*; and Fig. 107). They have been shown to occur in many bacilli and spirilla, but only in a few species of cocci. They vary in length, but may be several times the length of the bacterium, and may be at one or both extremities or all round. When terminal they may occur singly or there may be several. Sometimes complicated spiral tresses of free flagella are found in bacterial cultures; the development of these is difficult to explain. The nature of flagella has been much disputed. Some have held that, unlike what occurs in many algæ, they are not actual prolongations of the bacterial protoplasm, but merely appendages of the envelope, and have doubted whether they are really organs of locomotion. There is now, however, little doubt that they belong to the protoplasm. By appropriate means the central parts of the latter can be made to shrink away from the peripheral (*vide infra*, "plasmolysis"). In such a case movement goes on as before, and in stained preparations the flagella can be seen to be attached to the peripheral zone. It is to be noted that flagella have never been demonstrated in non-motile bacteria, while, on the other hand, they have been observed in nearly all motile forms. There is little doubt, however, that all cases of motility among the bacteria are not dependent on the possession of flagella, for in some of the special spiral forms, and in most

of the higher bacteria, motility is probably due to contractility of the protoplasm itself.

The Minuter Structure of the Bacterial Protoplasm.—Many attempts have been made to obtain deeper information as to the structure of the bacterial cell, especially with reference to the existence of a differentiation into nucleus and cytoplasm and as to the intimate phenomena of division. Observations bearing on such points can only be made on certain large species, but even with these, the minuteness of the cells makes the interpretation of the appearances seen most difficult. While bacterial protoplasm generally exhibits a selective action for nuclear aniline dyes, the material thus picked out appears in certain bacteria not to be uniformly distributed through the cell, but to be deposited in certain parts, and controversy has turned on the interpretation of such appearances. Two main views are at present held by different schools. Some consider that the bacterial cell contains a formed nucleus and a cytoplasm; at the same time it is questioned whether all the material giving the reaction of a nucleus is really part of such a central structure and not merely stored material. A modification of this view looks on the nucleus as an extended thread lying in the protoplasm,—in some bacillary types having a spiral or zigzag appearance. The other view is that the bacterial cell represents a vital unit in which differentiation into nucleus and cytoplasm has not yet occurred, and where the two main elements of higher cells are still intermingled with one another, the homologue of the cytoplasm being present in a close meshwork of nuclear material. With regard to the behaviour of the cell in division, amongst those who hold the former view some have figured appearances in the supposed nucleus which suggest the occurrence of mitosis, and others consider that before division there is a longitudinal splitting of the nuclear threads. All that can at present be certainly stated is that there is frequently in the bacterial protoplasm material which reacts to nuclear dyes, and material which does not so react, and that granules occur which probably represent material in process of transformation for the purposes of cellular nutrition.

Before bacteria exceeding, say, 1 to 1·5 μ in thickness were known, appearances analogous to those described had been recognised among the smaller forms, even when stained by ordinary methods. Occasionally irregular, deeply staining granules had been observed in the protoplasm, often, when they occurred in a bacillus, giving the latter the appearance of a short chain of minute cocci. These were called metachromatic granules from the fact that by appropriate procedure they could be stained with one dye, while the rest of the bacterial cell could be made to take on another colour. Such an appearance is well known as occurring in the diphtheria bacillus, especially when stained by Neisser's method (p. 114). In certain bacteria, for example the plague bacillus, the granules appear chiefly or solely at the poles and are often referred to as polar granules. It will be gathered from what has been said that at present it is impossible to interpret the significance of such granular structures. The appearances are present in certain bacteria under all circumstances, sometimes they are associated with growth in particular surroundings. In some species the presence of granules is an indication of lowered vitality.

Whatever the composition and relationships of the essential parts of the bacterial protoplasm may be, there is, as has been said, reason for

believing that even in the lower forms reserve material exists. This may consist of fat, glycogen, and other substances, amongst which may be mentioned volutin, as described by A. Meyer, a substance probably of proteid nature characterised by solubility in water, alkalies and acids, and by insolubility in alcohol.

In perfectly healthy and young bacteria, appearances of granule formation and of vacuolation may be artificially produced by physical means from the occurrence of what is known as *plasmolysis*. To speak generally, when a mass of protoplasm surrounded by a fairly firm envelope of a colloidal nature is placed in a solution containing salts in greater concentration than that in which it has previously been living, then by a process of osmosis the water held in the protoplasm passes out through the membrane, and, the protoplasm retracting from the latter, the appearance of vacuolation is presented. Now, in making a dried film for the microscopic examination of bacteria, the conditions necessary for the occurrence of this process may be produced, and the appearances of vacuolation and, in certain cases, of polar granules may thus be brought about. Plasmolysis in bacteria has been extensively investigated,[1] and has been found to occur in some species more readily than in others. Furthermore, it is often more readily observed in old or otherwise enfeebled cultures.

Bütschli, from a study of some large sulphur-containing forms, concludes that the greater part of the bacterial cell may correspond to a nucleus, and that this is surrounded by a thin layer of protoplasm which in the smaller bacteria escapes notice, unless when it can be made out at the ends of the cells. Fischer, it may be said, looks on the appearances seen in Bütschli's preparations as due to plasmolysis.

The Chemical Composition of Bacteria. — The chemical structure of bacterial protoplasm has been investigated both by micro- and macro-chemical methods,—the former being chiefly applicable to the larger forms. With iodine, granules staining brownish red or blue have been observed, and these are looked on as composed of substances allied to glycogen and starch respectively. Similarly, reactions with osmic acid, scharlach and similar dyes, have pointed to the presence of fats. While macro-chemical investigation has not thrown much light on the occurrence of carbohydrates, cellulose is said to be obtainable from certain bacteria. Bodies giving the reactions of fats have been isolated in bulk and have received much attention in the case of the tubercle bacillus group, whose special staining characteristics are probably due to bodies of this class. The substances mentioned are to be looked upon as reserve material or metabolic products in the life of the bacterial cell; but substances of a proteid nature have also been derived from bacterial protoplasm, and these are probably more intimately related to the vital structures of the organism. Chemically they are allied to, or are identical with, similar substances found

[1] Consult Fischer, "Untersuchungen über Bakterien," Berlin, 1894; "Ueber den Bau der Cyanophyceen und Bakterien," Jena, 1897.

in plant and animal tissues, for example, albumins, globulins, and phosphorised substances such as nucleins and nucleinic acid. There is also evidence that in the bacteria, as in the higher cells, lipoidal bodies are intimately associated with the proteid elements. Further, various mineral salts, especially those of sodium, potassium, and magnesium, are constituents of bacterial protoplasm. All the constituents show great variations, dependent not only on the species under investigation, but also on the composition of the culture media, on the temperature of growth, and on the age of the culture.

Many species of bacteria, when growing in masses, are brilliantly coloured, though few bacteria associated with the production of disease give rise to pigments. In some of the organisms classed as bacteria a pigment named bacterio-purpurin has been observed in the protoplasm, and similar intracellular pigments probably occur in some of the larger forms of the lower bacteria and may occur in the smaller; but it is usually impossible to determine whether the pigment occurs inside or outside the protoplasm. In many cases, for the free production of pigment abundant oxygen supply is necessary; but sometimes, as in the case of spirillum rubrum, the pigment is best formed in the absence of oxygen. Sometimes the faculty of forming it may be lost by an organism for a time, if not permanently, by the conditions of its growth being altered. Thus, for example, if the b. pyocyaneus be exposed to the temperature of 42° C. for a certain time, it loses its power of producing its bluish pigment. Pigments formed by bacteria often diffuse out into, and colour, the medium for a considerable distance around.

Comparatively little is known of the nature of bacterial pigments. Zopf, however, has found that many of them belong to a group of colouring matters which occur widely in the vegetable and animal kingdoms, namely, the lipochromes. These lipochromes, which get their name from the colouring matter of animal fat, include the colouring matter in the petals of Ranunculaceæ, the yellow pigments of serum and of the yolks of eggs, and many bacterial pigments. The lipochromes are characterised by their solubility in chloroform, alcohol, ether, and petroleum, and by their giving indigo-blue crystals with strong sulphuric acid, and a green colour with iodine dissolved in potassium iodide. Though crystalline compounds of these have been obtained, their chemical constitution is entirely unknown, and even their percentage composition is disputed.

The Classification of Bacteria.—In what we have to say under this heading we shall chiefly confine ourselves to the characters of the pathogenic bacteria. There have been numerous schemes set forth for the classification of bacteria, the

fundamental principle running through all of which has been the recognition of the two sub-groups and the type forms mentioned in the opening paragraph above. In the attempts to subdivide the group still further, scarcely two systematists are agreed as to the characters on which sub-classes are to be based. Our present knowledge of the essential morphology and relations of bacteria is as yet too limited for a really natural classification to be attempted. To prepare for the elaboration of the latter, there should be studied in every species the habitat, best food supply, condition as to gaseous environment, range of growth temperature, morphology, micro-chemical reactions, life-history, special properties, and pathogenicity (p. 136).

We must thus be content with a provisional and incomplete classification. We have said that the division into lower and higher bacteria is recognised by all, though, as in every other classification, transitional forms have to be accounted for. In subdividing the bacteria further, the forms they assume constitute at present the only practicable basis of classification. The lower bacteria thus naturally fall into the three groups mentioned, the cocci, bacilli, and spirilla, though the higher are more difficult to deal with. Subsidiary, though important, points in still further subdivision are the planes in which fission takes place and the presence or absence of spores. The recognition of actual species is often a matter of great difficulty. The points to be observed in this will be discussed later (p. 135).

I. The Lower Bacteria.[1]—These, as we have seen, are minute unicellular masses of protoplasm surrounded by an envelope, the total vital capacities of a species being represented in every cell. They present three distinct type forms, the coccus, the bacillus, and the spirillum; endogenous sporulation may occur. They may also be motile.

1. *The Cocci.*—In this group the cells range in different species from ·5 μ to 2 μ in diameter, but most measure about 1 μ. Before division they may increase in size in all directions. The species are usually classified according to the method of division. If the cells divide only in one axis, and through the consistency of their envelopes remain attached, then a chain of cocci will be formed. A species in which this occurs is known as a *streptococcus*. If division takes place irregularly, the resultant mass may be compared to a bunch of grapes, and the species is often called a *staphylococcus*. Division may take place in two axes at right angles to one another, in which case cocci adherent to each other

[1] For the illustration of this and the succeeding systematic paragraphs, *vide* Fig. 1.

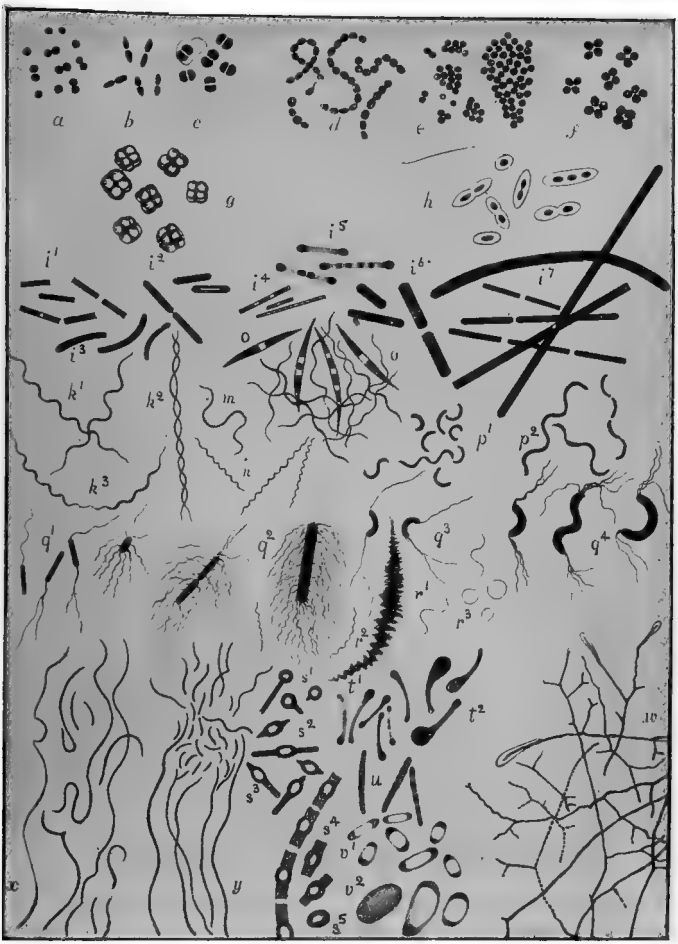

FIG. 1.—*a–h*. Different types of cocci. *a*. Single round cocci and simple diplococcal forms. *b*. Lancet-shaped cocci (type of pneumococcus). *c*. Biscuit cocci (gonococcus). *d*. Types of sporulation. s^1. Terminal. s^2, s^4. Mesial. s^3. Subterminal. s^5. Detached spores. t^1, t^2. Involution forms (b. diphtheriæ). *u*. Hofmann's bacillus. v^1–v^3. Involution forms (b. pestis). *w*. Streptothrix actinomyces. *x*. Leptothrix innominata. *y*. Thiothrix tenuis.

in packets of four (called *tetrads*) or sixteen may be found, the former number being the more frequent. To all these forms the word *micrococcus* is generally applied. The individuals in a growth of micrococci often show a tendency to remain united in twos. These are spoken of as *diplococci*, but this is not a distinctive character, since every coccus as a result of division becomes a diplococcus, though in some species the tendency to remain in pairs is well marked. The adhesion of cocci to one another depends on the character of the capsule. Often this has a well-marked outer limit (*micrococcus tetragenus*), sometimes it is of great extent, its diameter being many times that of the coccus (*streptococcus mesenterioides*). In none of the cocci have endogenous spores been certainly observed. The species of the streptococci and staphylococci differentiated number several hundreds. Usually included in this group are coccus-like organisms which divide in three axes at right angles to one another. These are referred to as *sarcinæ*. If the cells are lying single they are round, but usually they are seen in cubes of eight with the sides which are in contact slightly flattened. Large numbers of such cubes may be lying together. The sarcinæ are, as a rule, rather larger than the other members of the group. Most of the cocci are non-motile, but a few motile species possessing flagella have been described.

2. *Bacilli.*—These consist of long or short cylindrical cells, with rounded or sharply rectangular ends, usually not more than 1 μ broad, but varying very greatly in length. They may be motile or non-motile. Where flagella occur, these may be distributed all round the organism, or only at one or both of the poles. Several species are provided with sharply-marked capsules (b. pneumoniæ). In many species endogenous sporulation occurs. The spores may be central, terminal or subterminal, round, oval, or spindle-shaped. There is no doubt that among the bacilli in certain cases, *e.g.*, in b. diphtheriæ and b. tuberculosis, the phenomenon of true branching may occur. Such instances form a connecting link between the bacilli and the higher bacteria, *e.g.*, streptothrices.

Great confusion in nomenclature has arisen in this group in consequence of the different artificial meanings assigned to the essentially synonymous terms bacterium and bacillus. Migula, for instance, applies the former term to non-motile species, the latter to the motile. Hueppe, on the other hand, calls those in which endogenous sporulation does not occur, bacteria, and those where it does, bacilli. In the ordinary terminology of systematic bacteriology the word bacterium has been almost dropped, and is reserved, as we have done, as a general term for the whole group. It is usual to call all the rod-shaped varieties bacilli.

3. *Spirilla.*—These consist of cylindrical cells more or less spiral or wavy. Of such there are two main types. In one there is a long non-septate, usually slender, wavy or spiral thread (Fig. 1, *k*, *m*, *n*). In the other type the unit is a short curved rod (often referred to as of a "comma" shape). When two or more of the latter occur, as they often do, end to end with their curves alternating, then a wavy or spiral thread results. An example of this is the cholera microbe (Fig. 1, *p*). This latter type is of much more frequent occurrence. Among the first group motility is often not associated, as far as is known, with the possession of flagella. The cells here apparently move by an undulating or screw-like contraction of the protoplasm. Most of the motile spirilla, however, possess flagella. Of the latter there may be one or two, or a bunch containing as many as twenty, at one or both poles (Fig. 1, q^4). Division takes place as among the bacilli, but in some of the non-septate forms a longitudinal fission may occur. In some species endogenous sporulation has been observed.

Three terms are used in dividing this group, to which different authors have given different meanings. These terms are spirillum, spirochæte, vibrio. Migula makes "vibrio" synonymous with "microspira," which he applies to members of the group which possess only one or two polar flagella; "spirillum" he applies to similar species which have bunches of polar flagella, while "spirochæte" is reserved for the long unflagellated spiral cells. Hueppe applies the term "spirochæte" to forms without endospores, "vibrio" to those with endospores in which during sporulation the organism changes its form, and "spirillum" to the latter when no change of form takes place in sporulation. Flugge, another systematist, applies "spirochæte" and "spirillum" indiscriminately to any wavy or corkscrew form, and "vibrio" to forms where the undulations are not so well marked. It is thus necessary, in denominating such a bacterium by a specific name, to give the authority from whom the name is taken.

Within recent years doubt has arisen as to whether many of the non-septate spirillary forms, *e.g.*, *Spirochæte pallida*, are to be looked on as bacteria at all,—one view being that in, it may be, many cases they represent a stage in the life-history of what are really protozoa. The question is an important one, as these forms include many pathogenic agents. The ultimate classification of this group of bacteria must at present be left an open question, and it is convenient to denominate the non-septate spiral rods *Spirochætæ*, and those whose vital unit is a single curved rod *Spirilla*.

II. The Higher Bacteria.—These show advance on the lower in consisting of definite filaments branched or unbranched. In most cases the filaments at more or less regular intervals are

cut by septa into short rod-shaped or curved elements. Such elements are more or less interdependent on one another, and special staining methods are often necessary to demonstrate the septa which demarcate the individuals of a filament. There is further often a definite membrane or sheath common to all the elements in a filament. Not only, however, is there this close organic relationship between the elements of the higher bacteria, but there is also interdependence of function; for example, one end of a filament is frequently concerned merely in attaching the organism to some other object. The greatest advance, however, consists in the setting apart among most of the higher bacteria of the free terminations of the filaments for the production of new individuals, as has been described (p. 5). There are various classes under which the species of the higher bacteria are grouped; but our knowledge of them is still somewhat limited, as many of the members have not yet been artificially cultivated. The *beggiatoa* group consists of free swimming forms, motile by undulating contractions of their protoplasm. For the demonstration of the rod-like elements of the filaments special staining is necessary. The filaments have no special sheath, and the protoplasm contains sulphur granules. The method of reproduction is doubtful. The *thiothrix* group resembles the last in structure, and the protoplasm also contains sulphur granules; but the filaments are attached at one end, and at the other form gonidia. A *leptothrix* group is usually described which closely resembles the thiothrix group, except that the protoplasm does not contain sulphur granules. It cannot, however, be with certainty said whether such organisms can be sufficiently differentiated from the bacilli to warrant their being placed among the higher bacteria. In the *cladothrix* group there is the appearance of branching, which, however, is of a false kind. What happens is that a terminal cell divides, and on dividing again, it pushes the product of its first division to one side. There are thus two terminal cells lying side by side, and as each goes on dividing, the appearance of branching is given. Here, again, there is gonidium formation; and while the parent organism is in some of its elements motile, the gonidia move by means of flagella. The highest development is in the *streptothrix* group, to which belong the streptothrix actinomyces, or the actinomyces bovis, and several other important pathogenic agents. Here the organism consists of a felted mass of non-septate filaments, in which true dichotomous branching occurs. Under certain circumstances threads grow out, and produce chains of coccus-like bodies from which new individuals can be

reproduced. Such bodies are often referred to as spores, but they have not the same staining reactions nor resisting powers of so high a degree as ordinary bacterial spores. Sometimes, too, the protoplasm of the filaments breaks up into bacillus-like elements, which may also have the capacity of originating new individuals. In the streptothrix actinomyces there may appear a club-shaped swelling of the membrane at the end of the filament, which has by some been looked on as an organ of fructification, but which is most probably a product of a degenerative change, or possibly of defensive nature. The streptothrix group, though its morphology and relationships are much disputed, may be looked on as a link between the bacteria on the one hand, and the lower fungi on the other. Like the latter, the streptothrix forms show the felted mass of non-septate branching filaments, which is usually called a mycelium. On the other hand, the breaking up of the protoplasm of the streptothrix into coccus- and bacillus-like forms, links it to the other bacteria.

General Biology of the Bacteria.

There are five prime factors in the growth of bacteria which must be considered, namely, food supply, moisture, relation to gaseous environment, temperature, and light.

Food Supply.—The bacteria are chiefly found living on the complicated organic substances which form the bodies of dead plants and animals, or which are excreted by the latter while they are yet alive. Seeing that, as a general rule, many bacteria grow side by side, the food supply of any particular variety is, relatively to it, altered by the growth of the other varieties present. It is thus impossible to imitate the complexity of the natural food environment of any species. The artificial media used in bacteriological work may therefore be poor substitutes for the natural supply. In certain cases, however, the conditions under which we grow cultures may be better than the natural conditions. For while one of two species of bacteria growing side by side may favour the growth of the other, it may also in certain cases hinder it, and therefore, when the latter is grown alone it may grow better. Most bacteria seem to produce excretions which are unfavourable to their own vitality, for, when a species is sown on a mass of artificial food medium, it does not in the great majority of cases go on growing till the food supply is exhausted, but soon ceases to grow. Effete products diffuse out into the medium and prevent

growth. Such diffusion may be seen when the organism produces pigment, *e.g.*, b. pyocyaneus. In supplying artificial food for bacterial growth, the general principle ought to be to imitate as nearly as possible the natural surroundings, though it is found that there exists a considerable adaptability among organisms. With the pathogenic varieties it is usually found expedient to use media derived from the fluids of the animal body, and in cases where bacteria growing on plants are being studied, infusions of the plants on which they grow are frequently used. Some bacteria can exist on inorganic food, but most require organic material to be supplied. Of the latter, some require proteid to be present for their proper nourishment, while others can derive their nitrogen from a non-proteid such as asparagin. All bacteria require nitrogen to be present in some form, and many require to derive their carbon from carbohydrates. Mineral salts, especially sulphates, chlorides, and phosphates, and also salts of iron are necessary. Occasionally special substances are needed to support life. Thus some species, in the protoplasm of which sulphur granules occur, require sulphuretted hydrogen to be present. In nature the latter is usually furnished by other bacteria. Again the influenza bacillus must, outside the animal body, be provided with fresh blood or serum, and the growth of the gonococcus and the meningococcus is much favoured if serum be a constituent of a medium. The opinion has been expressed that vitamines are provided by such media. When the food supply of a bacterium fails, it degenerates and dies. The proof of death lies in the fact that when it is transferred to fresh and good food supply it does not multiply. If the bacterium forms spores, it may then survive the want of food for a very long time. It may here be stated that the reaction of the food medium is a matter of great importance. Most bacteria prefer a slightly alkaline medium, and some, *e.g.*, the cholera spirillum, will not grow in the presence of the smallest amount of free acid.

Moisture.—The presence of water is necessary for the continued growth of all bacteria. The amount of drying which bacteria in the vegetative stage will resist varies very much in different species. Thus the cholera spirillum is killed by two or three hours' drying, while the staphylococcus pyogenes aureus will survive ten days' drying, and the bacillus diphtheriæ still more. In the case of spores the periods are much longer. Anthrax spores will survive drying for several years, but here again moisture enables them to resist longer than when they are

quite dry. When organisms have been subjected to such hostile influences, even though they survive, it by no means follows that they retain all their vital properties.

Relation to Gaseous Environment.—The relation of bacteria to the oxygen of the air is such an important factor in the life of bacteria that it enables a biological division to be made among them. Some bacteria will only live and grow when free oxygen is present. To these the title of *obligatory aerobes* is given. Other bacteria will only grow when no free oxygen is present. These are called *obligatory anaerobes*. In still other bacteria the presence or absence of oxygen is a matter of indifference; such organisms are usually denominated *facultative anaerobes*,—they being preferably aerobic but capable of existing without oxygen. An example of an obligatory aerobe is b. subtilis; of an obligatory anaerobe, b. tetani, while the great majority of pathogenic bacteria are facultative anaerobes. The precise part played by oxygen tension in the growth of anaerobes may require further investigation, as, in certain species, anaerobiosis is a relative property. With regard to anaerobes, hydrogen and nitrogen are indifferent gases. Many anaerobes, however, do not flourish well in an atmosphere of carbon dioxide. Very few experiments have been made on the action on bacteria of gas under pressure. A great pressure of carbon dioxide is said to make the b. anthracis lose its power of sporing, but seems to have no effect on its vitality or on that of the b. typhosus; in the case of the bacillus pyocyaneus, however, such pressure is said to destroy life.

Temperature.—For every species of bacterium there is a temperature at which it grows best. This is called the "optimum temperature." There is also in each case a maximum temperature above which growth does not take place, and a minimum temperature below which growth does not take place. As a general rule the optimum temperature is about the temperature of the natural habitat of the organism. For organisms taking part in the ordinary processes of putrefaction the temperature of warm summer weather (20° to 24° C.) may be taken as the average optimum, while for organisms normally inhabiting animal tissues 35° to 39° C. is a fair average. The lowest limit of ordinary growth is from 12° to 14° C., and the upper is from 42° to 44° C. In exceptional cases growth may take place as low as 5° C., and as high as 70° C. Some organisms which grow best at a temperature of from 60° to 70° C. have been isolated from dung, the intestinal tract, etc. These have been called *thermophilic* bacteria. It is to be noted that while growth does not take place below or above

a certain limit, it by no means follows that death takes place outside such limits. Organisms can resist cooling below their minimum or heating beyond their maximum without being killed. Their vital activity is merely paralysed. Especially is this true of the effect of cold on bacteria. The results of different observers vary; but if we take as an example the cholera vibrio, Koch found that while the minimum temperature of growth was 16° C., a culture might be cooled to −32° C. without being killed. With regard to the upper limit, few ordinary organisms in a spore-free condition will survive a temperature of 57° C., if long enough applied. Many organisms lose some of their properties when grown at unnatural temperatures. Thus many pathogenic organisms lose their virulence if grown above their optimum temperature, and some chromogenic forms, most of which prefer rather low temperatures, lose their capacity of producing pigment, *e.g.*, spirillum rubrum.

Effect of Light.—Of recent years much attention has been paid to this factor in the life of bacteria. Direct sunlight is found to have a very inimical effect. It has been found that an exposure of dry anthrax spores for one and a half hours to sunlight kills them. When they are moist, a much longer exposure is necessary. Typhoid bacilli are killed in about one and a half hours, and similar results have been obtained with many other organisms. In such experiments the thickness of the medium surrounding the growth is an important point. Death takes place more readily if the medium is scanty or if the organisms are suspended in water. Any fallacy which might arise from the effect of the heat rays of the sun has been excluded, though light plus heat is more fatal than light alone. In direct sunlight it is chiefly the green, violet, and the ultra-violet rays which are fatal. The last-mentioned rays, however produced, have a powerful bactericidal action. By using a quartz spectrometer with a tungsten arc, Browning and Russ have recently shown that the ultra-violet rays with bactericidal action occupy a position in the spectrum at some distance from the visible rays—from 2960 to nearly 2100 Ångström units. The exact extent varies somewhat in the case of different organisms, but the area of rays in the spectrum effective against any one organism is comparatively sharply marked off. The bactericidal rays have little penetrating power, being completely absorbed by human skin in a thickness of 10 mm. These observers have also found that those, and only those, rays which are bactericidal to the staphylococcus aureus are absorbed by an emulsion of that organism. Diffuse daylight has also a bad effect upon

bacteria, though it takes a much longer exposure to do serious harm. A powerful electric light is as fatal as sunlight. Here, as with other factors, the results vary very much with the species under observation, and a distinction must be drawn between a mere cessation of growth and the condition of actual death. Some bacteria, especially occurring on the dead bodies of fresh fish, are phosphorescent.

Conditions affecting the Movements of Bacteria.—In some cases differences are observed in the behaviour of motile bacteria, contemporaneous with changes in their life-history. Thus, in the case of bacillus subtilis, movement ceases when sporulation is about to take place. On the other hand, in the bacillus of symptomatic anthrax, movement continues while sporulation is progressing. Under ordinary circumstances motile bacteria appear not to be constantly moving, but occasionally to rest. In every case the movements become more active if the temperature be raised. Most interest, however, attaches to the fact that bacilli may be attracted to certain substances and repelled by others. Schenk, for instance, observed that motile bacteria were attracted to a warm point in a way which did not occur when the bacteria were dead and therefore only subject to physical conditions. Most important observations have been made on the attraction and repulsion exercised on bacteria by chemical agents, which have been denominated respectively *positive* and *negative chemiotaxis.* Pfeffer investigated this subject in many lowly organisms, including bacterium termo and spirillum undula. The method was to fill with the agent a fine capillary tube, closed at one end, to introduce this into a drop of fluid containing the bacteria under a cover-glass, and to watch the effect through the microscope. The general result was to indicate that motile bacteria may be either attracted or repelled by the fluid in the tube. The effect of a given fluid differs in different organisms, and a fluid chemiotactic for one organism may not act on another. Degree of concentration is important, but the nature of the fluid is more so. Of inorganic substances, salts of potassium are the most powerfully attracting bodies, and in comparing organic bodies the important factor is the molecular constitution. Further, the filtered products of the growth of many bacteria have been found to have powerful chemiotactic properties. It is evident that all these observations have a most important bearing on the action of bacteria, though we do not yet know their true significance. Corresponding chemiotactic phenomena are shown also by certain animal cells, *e.g.*, leucocytes, to which reference is made below.

The Parts played by Bacteria in Nature.—As has been said, the chief effect of bacterial action in nature is to break up into more simple combinations the complex molecules of the organic substances which form the bodies of plants and animals, or which are excreted by them. That the very complicated process of putrefaction is due to bacteria is absolutely proved, for any organic substance can be preserved indefinitely from ordinary putrefaction by the adoption of some method of killing all bacteria present in it, as will be afterwards described. This statement, however, does not exclude the fact that molecular changes take place spontaneously in the passing of the organic body from life to death. Many processes not usually referred to as putrefactive are also bacterial in their origin, *e.g.*, the souring of milk, the becoming rancid of butter, etc. Bacterial action also underlies many processes of economic importance, such as the ripening of cream and of cheese, and the curing of tobacco.

A certain comparatively small number of bacteria have been proved to be the causal agents in some disease processes occurring in man, animals, and plants. This means that the fluids and tissues of living bodies are, under certain circumstances, a suitable pabulum for the bacteria involved. The effects of the action of these bacteria are analogous to those taking place in the action of the same or other bacteria on dead animal or vegetable matter. The complex organic molecules are broken up into simpler products. We shall study these processes more in detail later. Meantime we may note that the disease-producing effects of bacteria form the basis of another biological division of the group. Some bacteria are harmless to animals and plants, and apparently under no circumstances give rise to disease in either. These are known as saprophytes. They are normally engaged in breaking up dead animal and vegetable matter. Others normally live on or in the bodies of plants and animals and produce disease. These are known as parasitic bacteria. Sometimes an attempt is made to draw a hard-and-fast line between the *saprophytes* and the *parasites*, and obligatory saprophytes or parasites are spoken of. This is an erroneous distinction. Some bacteria which are normally saprophytes can produce pathogenic effects (*e.g.*, b. tetani), and it is consistent with our knowledge that the best-known parasites may have been derived from saprophytes. On the other hand, the fact that most bacteria associated with disease processes, and proved to be the cause of the latter, can be grown in artificial media, shows that for a time at least such parasites can be saprophytic. As to how far such a saprophytic existence of disease-producing

bacteria occurs in nature, we are in many instances still ignorant.

The Methods of Bacterial Action.—The processes which bodies undergo in being split up by bacteria depend, first, on the chemical nature of the bodies involved, and, secondly, on the varieties of the bacteria which are acting. The destruction of albuminous bodies which is mostly involved in the wide and varied process of putrefaction can be undertaken by whole groups of different varieties of bacteria. The action of the latter on such substances is analogous to what takes place when albumins are subjected to ordinary gastric and intestinal digestion. In these circumstances, therefore, the production of albumoses, peptones, etc., similar to those of ordinary digestion, can be recognised in putrefying solutions, though the process of destruction always goes further, and still simpler substances, *e.g.*, creatinin, indol, and, it may be, crystalline bodies of an alkaloidal nature, are the ultimate results. The process is an exceedingly complicated one when it takes place in nature, and different bacteria are probably concerned in the different stages. Many other bacteria, *e.g.*, some pathogenic forms, though not concerned in ordinary putrefactive processes, have a similar digestive capacity. When carbohydrates are being split up, then various alcohols, ethers, and acids (*e.g.*, lactic acid) are produced. During bacterial growth there is not infrequently the abundant production of such gases as sulphuretted hydrogen, carbon dioxide, methane, etc. One common result of bacterial action is thus an alteration of the reaction of a medium, sometimes towards the acid sometimes toward the alkaline side. Reduction phenomena are also frequently observed. For an exact knowledge of the destructive capacities of any particular bacterium there must be an accurate chemical examination of its effects when it has been grown in artificial media the nature of which is known. Many substances are produced by bacteria, of the exact nature of which we are still ignorant, for example, the toxic bodies which play such an important part in the action of many pathogenic species.

Many of the actions of bacteria depend on the production by them of *ferments* of a very varied nature and complicated action. Thus the digestive action on albumins probably depends on the production of a peptic ferment analogous to that produced in the animal stomach. Ferments which invert sugar, which split up sugars into alcohols or acids, which coagulate casein, which split up urea into ammonium carbonate, also occur.

Such ferments may be diffused into the surrounding fluid, or

be retained in the cells where they are formed. In the latter case the bacterial protoplasm often must be thoroughly disintegrated, *e.g.*, by grinding, before the ferment is liberated. Sometimes the breaking down of the organic matter appears to take place within, or in the immediate proximity of, the bacteria, sometimes wherever the soluble ferments reach the organic substances. And in certain cases the ferments diffusing out into the surrounding medium probably break down the constituents of the latter to some extent, and prepare them for a further, probably intracellular, disintegration. Thus, in certain putrefactions of fibrin, if the process be allowed to go on naturally, the fibrin dissolves and ultimately great gaseous evolution of carbon dioxide and ammonia takes place, but if the bacteria, shortly after the process has begun, are killed or paralysed by chloroform, then only a peptonisation of the fibrin occurs, without the further splitting up and gaseous production. That a purely intracellular digestion may take place is illustrated by what has been shown to occur in the case of the micrococcus ureæ, which from urea forms ammonium carbonate by adding water to the urea molecule. Here, if after the action has commenced the bacteria are filtered off, no further production of ammonium carbonate takes place, which shows that no ferment has been dissolved out into the urine. If now the bodies of the bacteria be extracted with absolute alcohol or ether, which of course destroy their vitality, a substance is obtained of the nature of a ferment, which, when added to sterile urine, rapidly causes the production of ammonium carbonate. This ferment has evidently been contained within the bacterial cells. According to some, the intracellular ferments alone have the capacity of initiating profound changes in material absorbed, while the easily diffusible agents have only a hydrolysing power. In the investigation of the phenomena of the ferment action of bacteria, it has been noted in certain cases that the ferments formed depend on the food supply offered to the bacterium. Thus in one case a bacterium growing in starch forms diastase, but it does not so do when grown on sugar.

The disintegration of organic material, which is so prominent an effect of bacterial growth, must be a by-effect in the synthesis of the complex substances of which the bacteria themselves are built up. The most striking example of such synthetic power is presented in the case of the bacteria which in the soil make nitrogen more available for plant nutrition by converting ammonia into nitrites and nitrates. Winogradski, by using media containing non-nitrogenous salts of magnesium, potassium, and ammonium, and free of organic matter, has demonstrated the existence of forms which convert, by oxidation, ammonia into nitrites, and of other forms which

convert these nitrites into nitrates. Both can derive their necessary carbon from alkaline carbonates. Other bacteria, or organisms allied to the bacteria, exist which can actually take up and combine into new compounds the free nitrogen of the air. These are found in the tubercles which develop on the rootlets of the leguminosæ. Without such organisms the tubercles do not develop, and without the development of the tubercles the plants are poor and stunted. Bacteria thus play an important part in the enrichment and fertilisation of the soil.

The Occurrence of Variability among Bacteria.—The question of the division of the group of bacteria into definite species has given rise to much discussion among vegetable and animal morphologists, and at one time very divergent views were held. Some even thought that the same species might at one time give rise to one disease,—at another time to another. There is, however, now practical unanimity that bacteria show as distinct species as the other lower plants and animals, though, of course, the difficulty of defining the concept of a species is as great in them as it is in the latter. Still, we can say that among the bacteria we see exhibited (to use the words of De Bary) "the same periodically repeated course of development within certain empirically determined limits of variation" which justifies, among higher forms of life, a species to be recognised. What at first raised doubts as to the occurrence of species among the bacteria was the observation in certain cases of what is known as *pleomorphism*. By this is meant that one species may assume at different times different forms, *e.g.*, appear as a coccus, a bacillus, or a leptothrix. This is especially the case with certain bacilli, and it may lead to such forms being classed among the higher bacteria. Pleomorphism is, however, a rare condition, and with regard to the bacteria as a whole we may say that each variety tends to conform to a definite type of structure and function which is peculiar to it and to it alone. On the other hand, slight variations from such type can occur in each. The size may vary a little with the medium in which the organism is growing, and under certain similar conditions the adhesion of bacteria to each other may also vary. Thus cocci, which are ordinarily seen in short chains, may grow in long chains. The capacity to form spores may be altered, and such properties as the elaboration of certain ferments or of certain pigments may be impaired. Also the characters of the growths on various media may undergo variations. As has been remarked, variation as observed consists largely in a tendency in a bacterium to lose properties ordinarily possessed, and all attempts to transform one bacterium into an apparently closely allied variety (such as the b. coli into the b. typhosus) have failed. This of course does not preclude the possibility of one species having been originally derived from another, or of both having descended from a common ancestor, but we can say that only variations of an unimportant order have been observed to take place, and here it must be remembered that in many cases we can have forty-eight or more generations under observation within twenty-four hours.

CHAPTER II.

METHODS OF CULTIVATION OF BACTERIA.

Introductory.—In order to study the characters of any species of bacterium, it is necessary to have it growing apart from every other species. In the great majority of cases where bacteria occur in nature, this condition is not fulfilled. Only in the blood and tissues in some diseases do particular species occur singly and alone. We usually have, therefore, to remove a bacterium from its natural surroundings and grow it on an artificial food medium. When we have succeeded in separating it, and have it growing on a medium which suits it, we are said to have obtained a *pure culture*. The recognition of different species of bacteria depends, in fact, far more on the characters presented by pure cultures and their behaviour in different food media, than on microscopic examination. The latter in most cases only enables us to refer a given bacterium to its class. Again, in inquiring as to the possible possession of pathogenic properties by a bacterium, the obtaining of pure cultures is absolutely essential.

To obtain pure cultures, then, is the first requisite of bacteriological research. Now, as bacteria are practically omnipresent, we must first of all have means of destroying all extraneous organisms which may be present in the food media to be used, in the vessels in which the food media are contained, and on all instruments which are to come in contact with our cultures. The technique of this destructive process is called sterilisation. We must therefore study the *methods of sterilisation*. The growth of bacteria in other than their natural surroundings involves further the *preparation of sterile artificial food media*, and when we have such media prepared we have still to look at the technique of the *separation of micro-organisms from mixtures of these, and the maintaining of pure cultures when the latter have been obtained*. We shall here find that different methods are necessary according as we are dealing with *aerobes*

or *anaerobes*. Each of these methods will be considered in turn.

The Methods of Sterilisation.

To exclude extraneous organisms, all food materials, glass vessels containing them, wires used in transferring bacteria from one culture medium to another, instruments used in making autopsies, etc., must be sterilised. These objects being so different, various methods are necessary, but underlying these methods is the general principle that all bacteria are destroyed by heat. The temperature necessary varies with different bacteria, and the vehicle of heat is also of great importance. The two vehicles employed are hot air and hot water or steam. The former is usually referred to as "dry heat," the latter as "moist heat." As showing the different effects of the two vehicles, Koch found, for instance, that the spores of bacillus anthracis, which were killed by moist heat at 100° C., in one hour, required three hours' dry heat at 140° C. to effect death. Both forms of heat may be applied at different temperatures—in the case of moist heat above 100° C., a pressure higher than that of the atmosphere must of course be developed.

A. *Sterilisation by Dry Heat.*

A (1). **Red Heat or Dull Red Heat.**—Red heat is used for the sterilisation of the platinum needles which, it will be found, are so constantly in use. A dull heat is used for cauteries, the points of forceps, and may be used for the incidental sterilisation of small glass objects (cover-slips, slides, occasionally when necessary even test-tubes), care of course being taken not to melt the glass. The heat is obtained by an ordinary Bunsen burner.

A (2). **Sterilisation by Dry Heat in a Hot-Air Chamber.**—The chamber (Fig. 2) consists of an outer and inner case of sheet iron. In the bottom of the outer there is a large hole. A Bunsen is lit beneath this, and thus plays on the bottom of the inner case, round all the sides of which the hot air rises and escapes through holes in the top of the outer case. A thermometer passes down into the interior of the chamber, halfway up which its bulb should be situated. It is found, as a matter of experience, that an exposure in such a chamber for one hour to a temperature of 160° C., is sufficient to kill all the organisms which usually pollute articles in a bacteriological laboratory, though circumstances might arise where this would

be insufficient. This means of sterilisation is used for the glass flasks, test-tubes, plates, Petri dishes, the use of which will be described. Such pieces of apparatus are thus obtained sterile and dry. It is advisable to put glass vessels into the chamber before heating it, and to allow them to stand in it after sterilisation till the temperature falls. Sudden heating or cooling is apt to cause glass to crack. The method is manifestly unsuitable for food media.

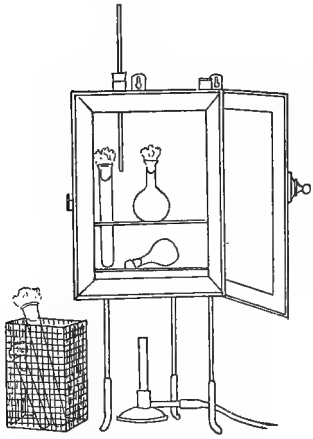

FIG. 2.—Hot-air steriliser.

B. *Sterilisation by Moist Heat.*

B (1). **By Boiling.** — The boiling of a liquid for five minutes is sufficient to kill ordinary germs if no spores be present, and this method is useful for sterilising distilled or tap water which may be required in various manipulations. To minimise rusting of knives and steel instruments it is well to boil the water for some time before placing them in it. Twenty minutes' boiling will here be sufficient. The boiling of any fluid at 100° C. for one and a half hours will ensure sterilisation under almost any circumstances.

B (2). **By Steam at 100° C.**—This is by far the most useful means of sterilisation. It may be accomplished in an ordinary potato steamer placed on a kitchen pot. The apparatus ordinarily used is "Koch's steam steriliser" (Fig. 3). This consists of a tall metal cylinder on legs, provided with a lid, and covered externally by some bad conductor of heat, such as felt or asbestos. A perforated tin diaphragm is fitted in the interior at a little distance above the bottom, and there is a tap at the bottom by which water may be supplied or withdrawn.

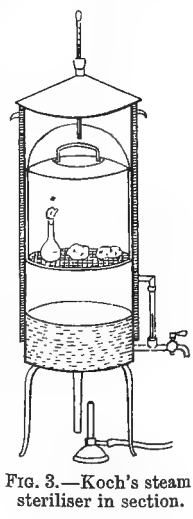

FIG. 3.—Koch's steam steriliser in section.

If water to the depth of 3 inches be placed in the interior and heat applied, it will quickly boil, and the steam streaming up will surround any flask or other object standing on the diaphragm. Here no evaporation takes place from any medium, as it is surrounded during sterilisation by an atmosphere saturated with water vapour. It is convenient to have the cylinder tall enough to hold a litre flask with a funnel 7 inches in diameter standing in its neck. The funnel may be supported by passing its tube through a second perforated diaphragm placed in the upper part of the steam chamber. With such a "Koch" in the laboratory a hot-water filter is not needed. As has been said, one and a half hour's steaming will sterilise any medium, but in the case of media containing gelatin such an exposure is not practicable, as, with long boiling, gelatin tends to lose its physical property of solidification. The method adopted in this case is to *steam for twenty minutes on each of three succeeding days.*

This is a modification of what is known as "Tyndall's intermittent sterilisation." The fundamental principle of this method is that all bacteria in a non-spored form are killed by the temperature of boiling water, while if in a spored form they may not be thus killed. Thus by the sterilisation on the first day all the non-spored forms are destroyed—the spores remaining alive. During the twenty-four hours which intervene before the next heating, these spores, being in a favourable medium, are likely to assume the non-spored form. The next heating kills these. In case any may still not have changed their spored form, the process is repeated on a third day. Experience shows that usually the medium can now be kept indefinitely in a sterile condition.

Steam at 100° C. is therefore available for the sterilisation of all ordinary media. In using the Koch's steriliser, especially when a large bulk is to be sterilised, it is best to put the medium in while the apparatus is cold, in order to make certain that the whole of the food mass reaches the temperature of 100° C. The period of exposure is reckoned from the time boiling commences in the water in the steriliser. At any rate, allowance must always be made for the time required to raise the temperature of the medium to that of the steam surrounding it.

B (3). **Sterilisation by Steam at High Pressure.**—This is the most rapid and effective means of sterilisation. It is effected in an autoclave (Fig. 4). This is a gun-metal cylinder supported in a cylindrical sheet-iron case; its top is fastened down with screws and nuts, and is furnished with a safety valve, pressure-gauge, and a thermometer. As in Koch's steriliser, the contents

are supported on a perforated diaphragm. The source of heat is a large Bunsen beneath. The temperature employed is usually 115° C. or 120° C. To boil at 115° C., water requires a pressure of about 23 lbs. to the square inch (*i.e.*, 8 lbs. plus the 15 lbs. of ordinary atmospheric pressure). To boil at 120° C., a pressure of about 30 lbs. (*i.e.*, 15 lbs. plus the usual pressure) is necessary. In such an apparatus the desired temperature is maintained by adjusting the safety-valve so as to blow off at the corresponding pressure. One exposure of media to such temperatures for a quarter of an hour is amply sufficient to kill all organisms or spores. Here, again, care must be taken when gelatin is to be sterilised. It must not be exposed to temperatures above 105° C., and is best sterilised by the intermittent method. Certain precautions are necessary in using the autoclave. In all cases it is necessary to allow the apparatus to cool well below 100° C. before opening it or allowing steam to blow off, otherwise there will be a sudden development of steam when the pressure is removed, and fluid media will be blown out of the flasks. Sometimes the instrument is not fitted with a thermometer. In this case care must be taken to expel all the air initially present, otherwise, a mixture of air and steam being present, the pressure read off the gauge cannot be accepted as an accurate indication of the temperature. Further, care must be taken to ensure the presence of a residuum of water when steam is fully up, otherwise the steam is superheated, and the pressure on the gauge again does not indicate the temperature correctly.

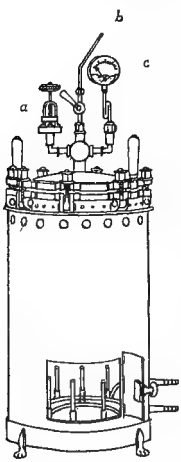

FIG. 4.—Autoclave.
a. Safety-valve.
b. Blow-off pipe.
c. Gauge.

B (4). **Sterilisation at Low Temperatures.**—Most organisms in a non-spored form are killed by a prolonged exposure to a temperature of 57° C. This fact has been taken advantage of for the sterilisation of blood serum, which will coagulate if exposed to a temperature above that point. Such a medium is sterilised on Tyndall's principle by exposing it for an hour at 57° C. for eight consecutive days, it being allowed to cool in the interval to the room temperature. The apparatus shown in Fig. 5 is a small hot-water jacket heated by a Bunsen placed beneath it, the temperature being controlled by a gas regulator.

To ensure that the temperature all around shall be the same, the lid also is hollow and filled with water, and there is a special gas burner at the side to heat it. This is the form originally used, but serum sterilisers are now constructed in which the test-tubes are placed in the sloped position, and in which inspissation (*vide* p. 40) can afterwards be performed at a higher temperature.

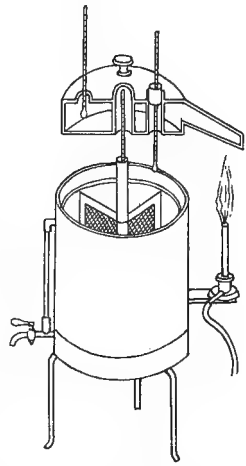

FIG. 5.—Steriliser for blood serum.

THE PREPARATION OF ORDINARY CULTURE MEDIA.

The general principle to be observed in the artificial culture of bacteria is that the medium used should approximate as closely as possible to that on which the bacterium grows naturally. In the case of pathogenic bacteria the medium therefore should resemble the juices of the body. The serum of the blood satisfies this condition, and is often used. Other media have been found which can support the life of all the pathogenic bacteria isolated. These consist of proteids or carbohydrates in a fluid, semi-solid, or solid form, in a transparent or opaque condition. The advantage of having a variety of media lies in the fact that growth characters on particular media, non-growth on some and growth on others, etc., constitute specific differences which are valuable in the identification of bacteria. The most commonly used media have as their basis a watery extract of meat. Most bacteria in growing in such an extract cause only a grey turbidity. A great advance resulted when Koch, by adding to it gelatin, provided a transparent solid medium in which growth characteristics of particular bacteria become evident. Many organisms, however, grow best at a temperature at which this nutrient gelatin is fluid, and therefore another gelatinous substance called agar, which does not melt below 98° C., was substituted. Bouillon made from meat extract, gelatin, and agar media, and the modifications of these, constitute the chief materials in which bacteria are grown.

Preparation of Meat Extract.

The flesh of the ox, calf, or horse is usually employed. Horse-flesh has the advantage of being cheaper and containing less fat than the others; though generally quite suitable, it has the disadvantage for certain purposes of containing a larger proportion of fermentable sugar. The flesh must be freed from fat, and finely minced. To a pound of mince add 1000 c.c. distilled water, and mix thoroughly in a shallow dish. Set aside in a cool place for twenty-four hours. Skim off any fat present, removing the last traces by stroking the surface of the fluid with pieces of filter paper. Place a clean linen cloth over the mouth of a large filter funnel, and strain the fluid through it into a flask. Pour the minced meat into the cloth, and, gathering up the edges of the latter in the left hand, squeeze out the juice still held back in the contained meat. Finish this expression by putting the cloth and its contents into a meat press (Fig. 6), similar to that used by pharmacists in preparing extracts; thus squeeze out the last drops. The resulting sanguineous fluid contains the soluble albumins of the meat, the soluble salts, extractives, and colouring matter, chiefly hæmoglobin. It is now boiled thoroughly for two hours, by which process the albumins coagulable by heat are coagulated. Strain now through a clean cloth, boil for another half-hour, and filter through white Swedish filter paper. Make up to 1000 c.c. with distilled water. The resulting fluid ought to be quite transparent, of a yellowish colour without any red tint. If there is any redness, the fluid must be reboiled and filtered till this colour disappears, otherwise in the later stages it will become opalescent. A large quantity of the extract may be made at a time, and what is not immediately required is put into a large flask, the neck plugged with cotton wool, and the whole sterilised by methods B (2) or (3). This extract contains very little albuminous matter, and consists chiefly of the soluble salts of the muscle, certain extractives, and altered colouring matters, along with any slight traces of soluble proteid not coagulated by heat. It is of acid reaction. We have now to see how, by the addition of proteid and other matter, it may be transformed into proper culture media.

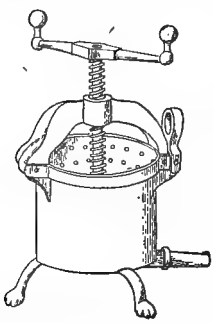

FIG. 6.—Meat press.

1. **Bouillon Media.**—These consist of meat extract with the addition of certain substances to render them suitable for the growth of bacteria.

1 (*a*). **Peptone Broth or Bouillon.**—This has the composition :—

Meat extract [1]	1000 c.c.
Sodium chloride . .	5 grms.
Peptone albumin [2] . . .	10 „

Boil till the ingredients are quite dissolved, and make slightly alkaline to litmus as directed below. After alkalinisation, filter through Swedish filter paper into flasks, make up to original volume with distilled water, plug the flasks with cotton wool, and sterilise by methods B (2) or (3) (pp. 28, 29).

In this medium the place of the original albumins of the meat is taken by peptone, a soluble protein not coagulated by heat. Here it may be remarked that the commercial peptone albumin is not pure peptone, but a mixture of albumoses (see footnote, p. 191) with a variable amount of pure peptone. The addition of the sodium chloride is necessitated by the fact that alkalinisation precipitates some of the phosphates and carbonates present. Experience has shown that sodium chloride can quite well be substituted. The reason for the alkalinisation is that it is found that most bacteria grow best on a medium slightly alkaline to litmus. Some, *e.g.*, the cholera vibrio, meningococcus, are very sensitive to the reaction of their surroundings.

Adjustment of the Reaction of Media.—The adjustment of the reaction of bacteriological media is a matter of great complexity. The method usually adopted with meat extract, which as prepared above is ordinarily slightly acid, is to add saturated sodium carbonate or sodium hydrate solution till the medium is slightly but distinctly alkaline to red litmus paper and no longer affects blue litmus paper. The occurrence of an amphoteric reaction—*i.e.*, one where red litmus is turned blue, and blue, red—is thus avoided. The test paper must be immersed in the liquid—on no account is the sampling to be done by transferring drops to the paper by means of a glass rod. The disadvantages of this method are that ordinary litmus is not a delicate indicator and, further, no standardisation of the proper tint to be aimed at is possible. The latter difficulty can be

[1] Some workers, instead of meat extract as made above, use Liebig's extract of beef, 2 grammes to the litre. While a medium made up in this way suffices for most of the commonly occurring pathogenic bacteria, it is advisable, in the case of the less robust organisms, to use media freshly made with meat.

[2] Whatever kind of peptone is used, it ought always to be tested for the absence of sugars and indol before being used for a medium. Chapetaut's, and also Savory and Moore's, peptone are recommended at present.

sufficiently got over by making up a solution of disodic phosphate ($Na_2HPO_4,2H_2O$), 11·876 grm. to the litre; test paper immersed in this assumes a tint just on the alkaline side of what is usually regarded as the optimum reaction for bacterial growth. In applying this method it is preferable to use azolitmin papers (made by immersing filter paper in 0·1 per cent. of the dye overnight and drying) or neutral-red papers (made by treating the paper with 0·02 per cent. neutral-red for three minutes). Both of these papers are more sensitive than ordinary litmus paper.

Eyre's Method.—Several methods have been introduced for adjusting the reaction by titration, and that of Eyre is widely used. It is applicable to any of the media ordinarily employed.

Preparation of Standard Solutions.—The first requisites here are normal solutions of acid and alkali. The latter is prepared as follows: 85 grammes of pure sodium bicarbonate are heated to dull redness for ten minutes in a platinum vessel and allowed to cool in an exsiccator. Just over 54 grammes of sodium carbonate should now be present; any excess is quickly removed, and the rest being dissolved in one litre of distilled water, a normal solution is obtained. A measured quantity is placed in a porcelain dish, and a few drops of a ·5 per cent. solution of phenol-phthalein in neutral methylated spirit is added to act as indicator. The alkali produces in the latter a brilliant rose-pink, which, however, disappears on the least excess of acid being present. The mixture is boiled and a solution of hydrochloric acid of unknown strength is run into the dish from a burette till the colour goes and does not return after very thorough stirring. The strength of the acid can then be calculated, and a normal solution can be obtained. From these two solutions any strength of acid or alkali (such as the decinormal solution of NaOH mentioned below) may be derived. The soda solutions are best stored in bottles with such a cork as is shown in Fig. 38; on the air inlet is placed a little bottle filled with soda lime and fitted with a similarly tubed cork. The CO_2 of the air which passes through is thus removed.

As Eyre has suggested, the reaction of a medium may be conveniently expressed by the sign + or − to indicate acid or alkaline respectively, and a number to indicate the number of cubic centimetres of normal alkaline or acid solution necessary to make a litre of the medium neutral to phenol-phthalein. Thus, for example, "reaction = − 15," will mean that the medium is alkaline, and requires 15 c.c. of normal HCl to make a litre neutral. It has been found that when a medium such as bouillon reacts neutral to litmus, its reaction to phenol-phthalein, according to the above standard, is on the average + 25. Now, as litmus was originally introduced by Koch, and as nearly all bacterial research has been done with media tested by litmus, it is evidently difficult to say exactly what precise

degree of alkalinity is the optimum for bacterial growth. It is probable that when a medium has been rendered neutral to phenol-phthalein by the addition of NaOH, the optimum degree is generally attained by the addition of from 10 to 15 c.c. of normal HCl per litre, *i.e.*, the optimum reaction is from + 10 to + 15. According to Fuller, the optimum reaction for bacterial growth lies about midway between the neutral point indicated by phenol-phthalein and the neutral point indicated by litmus.

Method.—The following procedure includes most of the improvements introduced by Eyre. The medium with all its constituents dissolved is filtered and then heated for about forty-five minutes in the steamer, the maximum acidity being reached after this time. Of the warm medium take 25 c.c. and put in a porcelain dish, add 25 c.c. distilled water, and 1 c.c. phenol-phthalein solution. Run in decinormal soda till neutral point is reached, indicated by the first trace of pink colour, the mixture being kept hot.[1] Repeat process thrice, and take the mean; this divided by 10 will give the amount (x) of *normal* soda required to neutralise 25 c.c. of medium; then $40x =$ amount necessary to neutralise a litre; and $40x - 10 =$ amount of normal soda necessary to give a litre its optimum reaction. Then measure the amount of medium to be dealt with, and add the requisite amount of soda solution.

Eyre uses a soda solution of ten times normal strength, which is delivered out of a 1 c.c. pipette divided into hundredths; this obviates, to a large extent, the error introduced by increasing the bulk of the medium if a weaker neutralising solution be used. In using these strong solutions care must be taken to remove any fluid adhering to the *outside* of the pipette. When the acid or alkali has been added the reaction of the medium must be again taken before sterilisation.

The present state of our knowledge of the principles involved in the proper adjustment of the reaction of media is not satisfactory.[2] The reaction of a medium depends on the hydrogen-ion concentration. The precise hydrogen-ion content of media as they are ordinarily prepared, either by the colorimetric or titration methods, has, however, not been

[1] The beginner may find considerable difficulty in recognising the first tint of pink in the yellow bouillon. A good way of getting over this is to take two samples of the medium, adding the indicator to one only; then to run the soda into these from separate burettes; for each few drops run into the medium containing the indicator the same amount is run into the other. Thus the recognition of the first permanent change in tint will be at once recognised by comparing the two samples.

[2] See Clark, *Journ. Infect. Dis.*, Chicago, vol. xvii. (1915), p. 109. For information regarding indicators, see Walpole, *Biochemical Journal*, vol. vii. (1913), p. 260; vol. viii. (1914), p. 628.

determined, and the optimum concentration for bacterial growth is unknown, though probably it approximates that of the blood serum. A still more serious difficulty is that no simple means is available for estimating the hydrogen-ion concentration of many media, *e.g.*, agar. It is nevertheless true that although the methods in use are largely empirical the products resulting are quite satisfactory for all but the more delicate bacteria dealt with. It is therefore probable that many organisms will tolerate a reaction which may extend from a point some way on the alkaline side of the optimum to a point some way on the acid side. Precise statements such as are frequently made regarding the adjustment of a medium to a certain reaction—say, on Eyre's scale—do not represent anything else than an expression of the fact that by the technique practised a suitable medium has been produced. It has not been usually recognised, for instance, that hydrogen-ion concentration is a function of the temperature at which the reaction has been adjusted. Thus, a reaction of, say, +10 adjusted at the boiling-point is no longer a +10 reaction at the incubation temperature at which the medium is actually used.

1 (*b*). **Glucose Broth.**—To the other constituents of 1 (*a*) there is added 1 or 2 per cent. of glucose. The steps in the preparation are the same. Glucose being a reducing agent, no free oxygen can exist in a medium containing it, and therefore glucose broth is used as a culture fluid for anaerobic organisms.

1 (*c*). **Glycerin Broth.**—The initial steps are the same as in 1 (*a*), but *after filtration* 6 to 8 per cent. of glycerin (sp. grav. 1·25) is added. This medium is especially used for growing the tubercle bacillus when the products of the growth of the latter are required.

2. **Gelatin Media.**—These are simply the above broths, with gelatin added as a solidifying body.

2 (*a*). **Peptone Gelatin** :—

Meat extract	1000 c.c.
Sodium chloride	5 grms.
Peptone albumin	10 „
Gelatin	100–150 „

(The "gold label" gelatin of Coignet et Cie, Paris, is the best.) The gelatin is cut into small pieces, and added with the other constituents to the extract; they are then thoroughly melted on a sand bath, or in the "Koch." The fluid medium is then rendered slightly alkaline, as in 1 (*a*), and filtered through filter paper. As the medium must not be allowed to solidify during the process, it must be kept warm. This is effected by putting the flask and funnel into a tall Koch's steriliser, in which case the funnel must be supported on a tripod or diaphragm, as there is great danger of the neck of the flask breaking if it has to support the funnel and its contents. The filtration may

also be carried out in a funnel with water-jacket which is heated, as shown in Fig. 7. Whichever instrument be used, before filtering shake up the melted medium, as it is apt while melting to have settled into layers of different density. Sometimes the first portion of filtrate is turbid. If so, replace it in the unfiltered part: often the subsequent filtrate in such circumstances is quite clear. A litre flask of the finished product ought to be quite transparent. If, however, it is partially opaque, add the white of an egg, shake up well, and steam thoroughly. The consequent coagulation of the albumin carries down the opalescent material, and, on making up with distilled water to the original quantity and refiltering, it will be found to be clear. The flask containing it is then plugged with cotton wool and sterilised, best by method B (2), p. 28. If the autoclave be used the temperature employed must not be above 105° C., and exposure not more than a quarter of an hour on three successive days. Too much boiling, or boiling at too high a temperature, as has been said, causes a gelatin medium to lose its property of solidification. The exact percentage of gelatin used in its preparation depends on the temperature at which growth is to take place. Its firmness is its most valuable characteristic, and to maintain this in hot summer weather, 15 parts per 100 are necessary. A limit is placed on higher percentages by the fact that, if the gelatin be too stiff, it will split on the perforation of its substance by the platinum needle used in inoculating it with a bacterial growth; 15 per cent. gelatin melts at about 24° C. For ordinary use in British laboratories 10 per cent. gelatin is a sufficient strength.

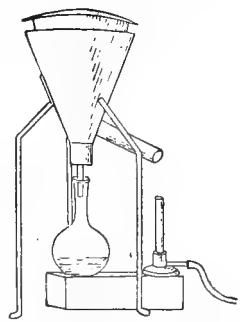

FIG. 7.—Hot-water funnel.

2 (*b*). **Glucose Gelatin.**—The constituents and mode of preparation are the same as 2 (*a*), with the addition of 1 to 2 per cent. of grape sugar before sterilisation. This medium is used for growing anaerobic organisms at the ordinary temperatures.

3. **Agar Media (French, "gélose").**—The disadvantage of gelatin is that at the blood temperature (38° C.), at which most pathogenic organisms grow best, it is liquid. To get a medium which will be solid at this temperature, agar is used as the stiffening agent instead of gelatin. Unlike the latter, which

is a proteid, agar is a carbohydrate. It is derived from the stems of various seaweeds growing in the Chinese seas, commercially classed together as "Ceylon Moss." For bacteriological purposes the dried stems of the seaweed may be used, but there is in the market a purified product in the form of a powder, which is preferable.

3 (*a*). **"Ordinary" Agar.**—This has the following composition :—

Meat extract	1000 c.c.
Sodium chloride . . .	5 grms.
Peptone albumin	10 „
Agar	15 „

Cut up the agar into very fine fragments (in fact till it is as nearly as possible dust), add to the meat extract with the other ingredients, and preferably allow to stand all night. Then boil gently in a "Koch" for two or three hours, till the agar is thoroughly melted. The process of melting may be hastened by boiling the medium in a sand bath and passing through it a stream of steam generated in another flask; the steam is led from the second flask by a bent glass tube passing from just beneath the cork to beneath the surface of the medium (Eyre). Render slightly alkaline with sodium hydrate solution, and if necessary make up to original volume with distilled water, and filter. Filtration here is a very slow process, and is best carried out in a tall Koch's steriliser. In doing this, it is well to put a glass plate over the filter funnel to prevent condensation water from dropping off the lid of the steriliser into the medium. If a slight degree of turbidity may be tolerated, it is sufficient to filter through a felt bag or jelly strainer. Plug the flask containing the filtrate, and sterilise either in autoclave for fifteen minutes or in Koch's steriliser for one and a half hours. Agar melts just below 100° C., and on cooling solidifies about 39° C.

3 (*b*). **Glycerin Agar.**—To 3 (*a*) after filtration add 6 to 8 per cent. of glycerin and sterilise as above. This is used especially for growing the tubercle bacillus.

3 (*c*). **Glucose Agar.**—Prepare as in 3 (*a*), but add 1 to 2 per cent. of glucose, or, better still, a corresponding amount of a 10 per cent. sterile solution of glucose after filtration. This medium is used for the culture of anaerobic organisms at temperatures above the melting-point of gelatin. For the growth of the tetanus bacillus a specially suitable medium is composed of meat extract with 2 per cent. agar, 2 per cent. peptone, and ·5 per cent. alkaline sodium phosphate added, and

made faintly alkaline to phenol-phthalein; 1 per cent. of glucose is added as above.

These bouillon, gelatin, and agar preparations constitute the most frequently used media. Growths in bouillon do not usually show any characteristic appearances which facilitate classification, but such a medium is of great use in investigating the soluble toxic products of bacteria. The most characteristic developments of organisms take place on the gelatin media. These have, however, the disadvantage of not being available when growth is to take place at any temperature above 24° C. For higher temperatures agar must be employed. Agar is, however, never so transparent. Though quite clear when fluid, on solidifying it always becomes slightly opaque. Further, growths upon it are never so characteristic as those on gelatin. It is, for instance, never liquefied, whereas some organisms, by their growth, liquefy gelatin and others do not — a fact of prime importance.

Special Culture Media.

An enormous variety of different media has been brought forward for use in cases either where special difficulty is experienced in getting an organism to grow, or where some special growth characteristic is to be studied. It is impossible to do more than give the chief of these.

Peptone Solution.

A simple solution of peptone (Witte) constitutes a suitable culture medium for many bacteria. The peptone in the proportion of 1 to 2 per cent., along with ·5 per cent. NaCl, is dissolved in distilled water by heating. The fluid is then filtered, placed in tubes, and sterilised. The reaction is usually distinctly alkaline, which condition is suitable for most purposes. For special purposes the reaction may be standardised. In such a solution the cholera vibrio grows with remarkable rapidity. It is also much used for testing the formation of indol by bacteria; and by the addition of one of the sugars to it the fermentative powers of an organism may be tested (p. 79). Litmus may be added to show any change in reaction.

Robertson's Bullock's Heart Medium.

This medium was introduced for the cultivation of anaerobes and is made as follows: 8 oz. of bullock's heart is minced very

finely and then ground in a mortar; 8 oz. of tap water are added and the mixture is heated slowly so as to cook the meat thoroughly; normal sodium hydrate is added until the reaction is alkaline to litmus. The medium is divided into tubes and autoclaved. It can be adapted for growing cultures of anaerobes in the ordinary atmosphere by running a little sterile liquid paraffin on to its surface.

Media containing an Indicator.

Litmus Media.—To any of the ordinary media litmus (French, tournesol) may be added to show change in reaction during bacterial growth. The litmus is added, before sterilisation, as a strong watery solution (*e.g.*, the Kubel-Tiemann solution, *vide* p. 50) in sufficient quantity to give the medium a distinctly bluish tint. During the development of an acid reaction the colour changes to a pink, and may subsequently be discharged.

Neutral-Red Media.—This dye was introduced by Grünbaum and Hume as an aid in determining the presence or absence of members of the b. coli group, especially in the examination of water. The media found most suitable are agar or bouillon containing ·5 per cent. of the sugar to be tested, to which ·5 per cent. of a 1 per cent. watery solution of neutral-red is added. The alkaline medium is of a yellowish brown colour which in the presence of acid passes into a deep rose red. Sometimes there subsequently occurs a change to a fluorescent green, caused apparently by a change in the composition of the dye, as the fluorescence is not discharged by addition of alkali. (See also p. 356.)

Blood Serum Media.

Solidified Blood Serum.—Koch introduced this medium for the cultivation of the tubercle bacillus and in order to obtain it in a comparatively clear state, adopted the method of inspissation at 65° C. after sterilising by the intermittent method at low temperature—B (4) (p. 30). The procedure is somewhat tedious, and for all ordinary purposes opaque coagulated serum, sterilised by the usual methods, can be substituted. A sufficient quantity of serum is placed in a series of sterile test-tubes; these are then placed in a sloped tray, put in the steam steriliser, and steamed for an hour. We have found the following method, however, to give the best results. The serum in test-tubes is first thoroughly inspissated, in the sloped position, at 65° C.

Sufficient sterile ·8 per cent. sodium chloride is added to each tube to cover the medium in the upright position. The tubes are then sterilised in this position in the autoclave for a quarter of an hour at 115° C. and thereafter stored. When a tube is to be used the saline is poured off. The advantages of this method are that complete sterility is readily obtained and the medium does not dry up.

Koch's Method. — Plug the mouth of a tall cylindrical glass vessel (say of 1000 c.c. capacity) with cotton wool, and sterilise by steaming it in a Koch's steriliser for one and a half hours. Take it to the place where a horse, ox, or sheep is to be killed. When the artery or vein of the animal is opened, allow the first blood which flows, and which may be contaminated from the hair, etc., to escape ; fill the vessel with the blood subsequently shed. Carry carefully back to the laboratory without shaking, and place for twenty-four hours in a cool place, preferably an ice chest. The clear serum will separate from the clotted blood. The serum obtained by such means is frequently contaminated with bacteria. These can be removed by filtration through an earthenware candle, and this can be rapidly effected by using an arrangement such as that shown in Fig. 27, the serum during filtration being kept at about 55° C. With a sterile 10 c.c. pipette, transfer this quantity of serum to each of a series of test-tubes which must previously have been sterilised by dry heat. The serum may, with all precautions, have been contaminated during the manipulations, and must be sterilised. As it will coagulate if heated above 68° C., advantage must be taken of the intermittent process of sterilisation at 57° C. [method B (4)]. It is therefore kept for one hour at this temperature on each of eight successive days. The medium should be incubated for a day at 37° C. before use, to see that the result

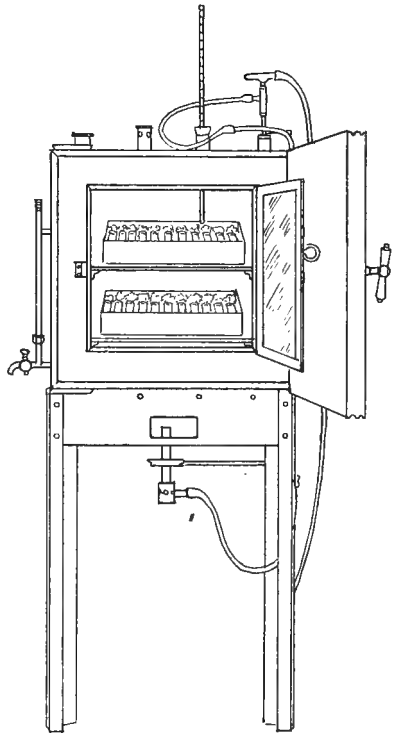

FIG. 8.—Blood serum inspissator.

is successful. After sterilisation it is "inspissated," by which process a clear solid medium is obtained. "Inspissation" is an initial stage of coagulation, and is effected by keeping the serum at 65° C. till it stiffens. This temperature is just below the coagulation point of the serum. The more slowly the operation is performed the clearer will be the serum. The apparatus used for the purpose is one of the various forms of serum steriliser (*e.g.*, Fig. 8), generally a chamber with water-jacket heated with a Bunsen below. The temperature is controlled by a gas regulator, and such an apparatus can, by altering the temperature, be used either for sterilisation or inspissation.

Löffler's Blood Serum.—This is the best medium for the growth of the b. diphtheriæ, and may be used for other organisms. It has the following composition: Three parts of calf's or lamb's blood serum are mixed with one part ordinary neutral peptone bouillon made from veal with 1 per cent. of grape sugar added to it. Though this is the original formula, it can be made from ox or sheep serum and beef bouillon without its qualities being markedly impaired. Sterilise as in the case of solidified blood serum (p. 40).

Alkaline Blood Serum (Lorrain Smith's Method).—To each 100 c.c. of the serum obtained as before, add 1 to 1·5 c.c. of a 10 per cent. solution of sodium hydrate and shake gently. Put sufficient of the mixture into each of a series of test-tubes, and, laying them on their sides, sterilise by method B (2). If the process of sterilisation be carried out too quickly, bubbles of gas are apt to form before the serum is solid, and these interfere with the usefulness of the medium. This can be obviated if the serum be solidified high up in the Koch's steriliser, in which the water is allowed only to simmer. In this case sterilisation ought to go on for one and a half hours. A clear solid medium (consisting practically of alkali-albumen) is thus obtained, and is of value for the growth of the organisms for which Koch's serum is used, and especially for the growth of the b. diphtheriæ. Its great advantage is that aseptic precautions in obtaining blood from the animal are not necessary, and it is easily sterilised.

Marmorek's Serum Media.—Marmorek succeeded in maintaining the virulence of cultures of pyogenic streptococci by growing them on the following media, which are arranged in the order of their utility:—

1. Human serum 2 parts, bouillon 1 part.
2. Pleuritic or ascitic serum 1 part, bouillon 2 parts.
3. Asses' or mules' serum 2 parts, bouillon 1 part.
4. Horse serum 2 parts, bouillon 1 part.

Sterile ox serum may be used in a similar way. In the case

of these media, sterilisation is effected by method B (4), and they are used fluid.

Serum Media for Gonococcus.—The following media will be found suitable :—

Wertheim's Medium consists of one part of sterile human serum and two parts of peptone agar. The agar is melted in tubes and allowed to cool to 45° C. ; the serum warmed to the same temperature is then added, and the mixture is allowed to solidify in the sloped position. Human serum may be conveniently obtained from placental blood or from blood drawn off for the Wassermann reaction.

Gurd's Medium is a 2 per cent. agar with acid reaction +6 to phenolphthalein (p. 34), with defibrinated human blood added in the proportion of about 5 drops to 5 c.c. of agar ; the blood is added to the melted agar as in Wertheim's medium. W. B. M. Martin recommends the substitution of sodium phosphate (·5 per cent.) for sodium chloride in the preparation of the agar, and uses fluid human serum sterilised at 57° C. in place of blood. He also finds that the same agar medium allowed to solidify and then smeared on the surface with a drop or two of human serum or blood gives excellent results.

Thomson's Medium.—This is an agar medium with the addition of human plasma. Nutrient agar (2·5 per cent.) is prepared in the usual way from meat juice with 1 per cent. of Witte's peptone added and its reaction brought to +6. But instead of the usual 0·5 per cent. sodium chloride, the salts of Ringer's solution are added, namely, sodium chloride 9 grms., calcium hcloride 0·25 grm., and potassium chloride 0·42 grm., per litre. Glucose in the proportion of 2·5 per cent. is also added. The medium is then sterilised and tubed—4 c.c. in each tube.

To obtain the plasma a tubeful of human blood is drawn off as for a Wassermann reaction. About 10 c.c. are poured at once into a centrifuge tube containing 2 c.c. of a 2 per cent. of sodium chloride solution, to prevent clotting, and fitted with a sterile cork. The blood is then centrifuged till the corpuscles are thrown down. The agar medium in tubes is melted and its temperature brought to 50° C. To each tube is then added with a sterile pipette 1 c.c. of plasma, and the mixture is allowed to solidify in the sloped position. The medium gives a very abundant growth, and is very suitable for the preparation of vaccines.

Any of these media may be used for plate cultures, the agar being melted and cooled to 45° C. as for agar plates ; the serum or blood is then added, and the mixture is poured out in Petri dishes.

Medium for Meningococcus.—*Trypagar.*—Gordon has introduced this medium for the cultivation of the meningococcus. It is prepared as follows :—

1. Take 50 grms. of pea flour (ordinary Pearce Duff's) and add to 1 litre of distilled water with 100 grms. of salt. Mix and steam for half an hour, stirring occasionally ; allow to settle, and filter, then sterilise and label "Saline Pea Extract." This pea extract should preferably be freshly made for each batch of agar.

2. Take some fresh bullocks' hearts, free from fat and vessels, mince the meat very finely, and weigh. To each ½ kilo add 1 litre of water,

and make faintly alkaline to litmus with 20 per cent. caustic potash solution. Heat this slowly to 75°–80° C. for 5 minutes. Cool to 37° C., and add 1 per cent. of Liquor Trypsinæ Co. (Allen & Hanbury), and keep it at 37° for 2½ to 3 hours. When trypsinising is finished, test for peptone with copper sulphate and caustic potash as below, then render slightly acid with glacial acetic acid, and bring slowly to the boil for a quarter of an hour. Leave overnight in a cool place, and siphon off the clear liquid in the morning. Make this faintly alkaline to litmus, and sterilise in the autoclave at 118° C. for 1 hour on each of two days (if not to be used at once). The result is trypsinised broth.

To make Trypagar.—Take a measured quantity of the trypsinised broth, add 2 per cent. of agar fibre (see below for preparation), and ·215 grm. of calcium chloride per litre. Autoclave at 118° C. for three-quarters of an hour to dissolve the agar. Mix together in an urn or saucepan; titrate with $\frac{N}{10}$ caustic soda while boiling, using phenolphthalein as the indicator, and add the necessary amount of normal caustic potash to give an absolutely neutral reaction. Cool to 60° C., add white of egg (2 to a litre) beaten up with the crushed shells, autoclave again at 118° C. for 75 minutes (or in the steamer for 2 hours). Filter, add to the filtrate 5 per cent. of the sterile pea extract, and sterilise in the ordinary way. For use, a small quantity of sterile rabbit's blood or serum—5 c.c. to 200 c.c. of medium—is added to the medium in the melted state at 50° C. before being poured into capsules, or a drop or two of serum may be spread with a glass rod over the surface of the medium after it has solidified.

Preparation of Fibre Agar.—Weigh out the required quantity, cut up small with scissors, place in a large flask or enamel pail, and wash twice quickly in water. Drain thoroughly; add water just to cover, and put in glacial acetic acid, 2·5 c.c. per litre of water. Mix thoroughly and leave for a quarter of an hour. Pour off the liquid and wash *thoroughly* four or five times to make sure that all the acetic acid is washed out. Drain carefully, and use as above.

Biuret Reaction for Peptone.—Take 5 c.c. of broth, add 1 c.c. of 5 per cent. solution of copper sulphate. Mix, and then add 5 c.c. normal caustic potash. A true pink colour indicates that trypsinisation is sufficient; a bluish-purple shade, that it is incomplete.

Blood Media.

Blood-Smeared Agar.—This medium was introduced by Pfeiffer for growing the influenza bacillus, and it has been used for the organisms which do not readily grow on the ordinary media, *e.g.*, the gonococcus and the pneumococcus. Human blood or the blood of animals may be used. "Sloped tubes" (*vide* p. 54) of agar are employed (glycerin agar is not so suitable). Purify a finger first with 1–1000 corrosive sublimate, dry, and then wash with absolute alcohol to remove the sublimate. Allow the alcohol to evaporate. Prick with a needle sterilised by heat, and, catching a drop of blood in the loop of a sterile platinum wire, smear it on the surface of the agar.

The excess of the blood runs down and leaves a film on the surface. Cover the tubes with indiarubber caps, and incubate them for one or two days at 37° C. before use, to make certain that they are sterile. Agar poured out in a thin layer in a Petri dish may be smeared with blood in the same way and used for cultures.

Serum-Smeared Agar is prepared in a similar way by smearing the surface of the agar with blood serum, or by adding a few drops of serum to the tube and then allowing it to flow over the surface.

Blood Agar.—For many purposes (*e.g.*, the growth of the whooping-cough bacillus, the bacillus of soft sore, the cultivation of trypanosomes and Leishmaniæ), the use of agar containing defibrinated blood, especially rabbit blood, is desirable. The blood may be obtained in several ways, preferably by bleeding from the carotid. For this purpose the vessel is exposed and as long a portion as possible is cleaned. This is ligatured high up, and a ligature is loosely applied round the lower part of the vessel in such a way as not to constrict it. The vessel is clamped above this ligature, and with scissors an oblique opening is made in its side. The clamp being removed, the stream of blood is directed by means of the ligature into the mouth of a stout sterile flask, which ought to contain some fragments of broken glass rod. During the bleeding the flask should be gently agitated, and when filled should be shaken in a bath of water just below blood-heat. We have found that sterile blood can be obtained from the ear vein of the rabbit by the method of bleeding to be subsequently described (p. 126). The ear is well washed with lysol, the lysol dried off with sterile wool, absolute alcohol dropped on and allowed to evaporate, and the blood withdrawn. The first c.c. or so is rejected.

However the blood is obtained, after defibrination it is warmed to 45° C., and added to agar of the same temperature in the proportion of about one-third of blood and two-thirds of agar. Needless to say, such media must be incubated before use to ensure that bacteria have not gained access during preparation.

Bordet and Gengou's Medium for Bacillus of Whooping-Cough.—An extract of potato is first prepared by adding two parts of water containing 4 per cent. of glycerin to one part of potato chips; the mixture is then boiled and the fluid is separated off. An agar medium is then prepared of the following composition: potato extract, 50 c.c.; ·6 per cent. solution of sodium chloride, 150 c.c.; and agar, 5 grms. Of this medium, 2–3 c.c. are placed in each of a series of sterile test-tubes, and then to each there is added, by the method described in the preceding paragraph, an equal part of defibrinated rabbit's (or better, human) blood, obtained

by aseptic methods. The mixture is then allowed to solidify in the sloped position. This medium is also very suitable for the growth of the gonococcus, meningococcus, and influenza bacillus.

Blood-Alkali Agar (Dieudonné).—This medium, introduced for the culture of the cholera spirillum, for which purpose it has been found extremely suitable, has the property of inhibiting the growth of most of the intestinal bacteria; for example, the b. coli does not grow on it, or does so very slightly. A blood-alkali solution is prepared by adding equal parts of defibrinated ox blood and of normal caustic soda solution; the solution may then be sterilised in the steam steriliser. Of this solution three parts are added to seven parts of ordinary peptone-agar rendered neutral to litmus, and the mixture is disposed in test-tubes.

Novy and MacNeal's Medium for Culture of Trypanosomes.—125 grammes rabbit or ox flesh are treated with 1000 c.c. distilled water, as in making ordinary bouillon, and there are added to the meat extract 20 grms. Witte's peptone, 5 grms. sodium chloride, 20 grms. agar, and 10 c.c. normal sodium carbonate. The medium is placed in tubes and sterilised in the autoclave at 110° C. for thirty minutes. It is cooled at 50° C., and there is added to the medium in each tube twice its volume of defibrinated rabbit blood, which has been prepared with all aseptic precautions; the tubes are allowed to set in the inclined position. In inoculating such tubes they are placed in an upright position for a few minutes, and then the infective material is introduced.

Hiss's Serum Water Media.—These are composed of one part of ox's serum and three parts of distilled water with 1 per cent. litmus; various sugars in a pure condition are added in the proportion of 1 per cent. (see p. 78). The development of acid by fermentation is shown by the alteration of the colour and by coagulation of the medium. These media do not coagulate at 100° C., and thus can be sterilised in the steam steriliser. They have been extensively used by American workers in studying the fermentative properties of the b. dysenteriæ, b. coli, etc.

Egg Media.

Within recent years media containing either the yolk, or both the yolk and the white of egg, have been used for the culture of the tubercle bacillus by Dorset and others. The following will be found very suitable:—

Dorset's Egg Medium.—The contents of four fresh eggs are well beaten up, 25 c.c. of water are added and thoroughly mixed, the mixture being passed through muslin to remove air bells. The fluid is then filled into tubes, and these are heated for four hours in the sloped position at 70° C. Another method of solidifying the medium is to place the tubes high up in a Koch's steriliser for 3–5 minutes. In either case the medium may then be covered with ·8 per cent. sodium chloride solution and sterilised in the autoclave (p. 29). Before the inoculation of a tube, two drops of sterilised water are placed on the surface. The inoculation material is well rubbed over the surface of the medium, the tubes are sealed with a few

drops of paraffin on the top of the plug and are incubated in the sloped position. The addition of a sufficient quantity of a solution of basic fuchsin to colour the medium a pale pink is of advantage, as it makes the early growths more easily seen (Cruickshank).

Glycerin Egg Medium (Lubenau).—200 c.c. of 5 per cent. glycerin bouillon, 1·5 per cent. acid to phenol-phthalein, are added to ten fresh eggs beaten up, and are thoroughly mixed. The medium is then treated as above. An equally good medium may be prepared by adding one part of 6 per cent. glycerin, in ·8 per cent. sodium chloride solution, to three parts of beaten egg.

Potatoes as Culture Material.

Potatoes are best used as slices in tubes, according to the method introduced by Ehrlich. A large, long potato is well washed and scrubbed, and peeled with a clean knife. A cylinder is then bored from its interior with an apple corer or a large cork borer, and is cut obliquely, as in Fig. 9. Two wedges are thus obtained, each of which is placed broad end downward in a test-tube of special form (see Fig. 10). In the wide part at the bottom of this tube is placed a piece of cotton wool, which catches any condensation water which may form. The wedge rests on the constriction above this bulbous portion. The tubes, washed, dried, and with cotton wool in the bottom and in the mouth, are sterilised before the slices of potato are introduced. After the latter are inserted, the tubes are sterilised in the Koch steam steriliser for one hour, or in the autoclave for fifteen minutes, at 115° C. An ordinary test-tube may be used with a piece of sterile absorbent wool in its bottom, on which the potato may rest.

FIG. 9.—Cylinder of potato cut obliquely.

FIG. 10.—Ehrlich's tube, containing piece of potato.

Glycerin potato, suitable for the growth of the tubercle bacillus, may be prepared by covering the slices in the tubes with 6 per cent. solution of glycerin in water, and steaming for half an hour. The fluid is then poured off and the sterilisation continued for another half-hour.

Potatoes ought not to be prepared long before being used, as the surface is apt to become dry and

discoloured. It is well to take the reaction of the potato with litmus before sterilisation, as this varies; normally in young potatoes it is weakly acid. The reaction of the potato may be more accurately estimated by steeping a given weight of potato slices for some time in a known quantity of distilled water, and then estimating the reaction of the water by phenolphthalein. The required degree of acidity or alkalinity is obtained by adding the necessary quantity of HCl or NaOH solution (p. 34), and steeping again. The water is then poured off and the potatoes placed in tubes. Potatoes before being inoculated ought always to be incubated at 37° C. for a night, to make sure that the sterilisation has been successful.

Milk as a Culture Medium.

This is a convenient medium for observing the effects of bacterial growth, in coagulating the soluble albumin, and in fermenting the lactose. It is prepared as follows: Fresh milk is taken, preferably after having had the cream "separated" by centrifugalisation, and is steamed for fifteen minutes in the Koch; it is then set aside in an ice chest or cool place overnight to facilitate further separation of cream. The milk is siphoned off from beneath the cream and placed in sterile test-tubes. A little litmus, sufficient to tint the milk, is often added before final sterilisation to show change in reaction produced by bacterial growth—*litmus milk*. The reaction of fresh milk is alkaline. If great accuracy is necessary, any required degree of reaction may be obtained by the titration method. It is then placed in tubes, and sterilised by methods B (2) or B (3).

Bread Paste.

This is useful for growing torulæ, moulds, etc. Some ordinary bread is cut into slices, and then dried in an oven till it is so dry that it can be pounded to a fine powder in a mortar, or rubbed down with the fingers and passed through a sieve. Some 100 c.c. flasks are washed, dried, and sterilised, and a layer of the powder half an inch thick placed on the bottom. Distilled water, sufficient to cover the whole of it, is then run in with a pipette held close to the surface of the bread, and, the cotton-wool plugs being replaced, the flasks are sterilised in the Koch's steriliser by method B (2). The reaction is slightly acid.

Media used for separating the Members of Bacterial Groups.

A great number of media have been devised for use in differentiating the members of the coli-typhoid and other bacterial groups. The general feature of these media is that they contain certain substances, often sugars, which tend to bring out the special characters of the organism under investigation. Sometimes also substances are present which inhibit the growth of bacteria other than those belonging to the group. The following are the media which here deserve most attention :—

MacConkey's Bile-Salt Media.—These media were introduced for the purpose of differentiating the intestinal bacteria, and have been extensively used for the study of the b. coli, b. typhosus, b. dysenteriæ, etc. The characteristic ingredients are bile salts and various sugars. The stock solution is the following: Commercial sodium taurocholate, ·5 gramme; Witte's peptone, 2 grms.; tap water, 100 c.c. (if distilled water be used, ·03 per cent. of calcium chloride should be added). The solution is steamed for two hours, filtered when hot, allowed to stand for twenty-four hours or till sedimentation has occurred, and filtered again. For a liquid medium there is added to this ·25 per cent. of a freshly prepared 1 per cent. solution of neutral red and the sugar,—when glucose, dulcite, or adonite is used, ·5 per cent. is added, in the case of other sugars 1 per cent. The fluid is distributed in Durham's fermentation tubes and sterilised in the steamer for ten minutes on two successive days, care being taken not to overheat the medium.

For bile-salt agar 1·5 to 2 per cent. agar is dissolved in the stock solution in the autoclave, if necessary cleared with white of egg and filtered. Neutral red and a sugar are added, as in the case of the liquid medium. It is well to sterilise it in flasks containing 80 c.c., this being an amount sufficient for three large Petri capsules. When this medium is used for examining urine or fæces, plates are inoculated as with Drigalski's medium (*infra*); for its use in water examinations, see p. 152.

When growth of a bacterium producing acid and gas occurs in neutral-red fluid media the latter turns a rose colour, and gas appears in the Durham's tube. Sometimes a fluorescent appearance is also observed, the significance of which will be discussed in the chapter on B. coli. With the neutral-red solid media the colonies of any organism giving rise to acid will be of a rose-red colour. Litmus is often used instead of neutral red.

Drigalski and Conradi's Medium.—This is one of the media used for the study of intestinal bacteria, and especially for the isolation of the typhoid group of organisms. (*a*) Three pounds of meat are treated with two litres of water overnight; the fluid is separated as usual, boiled for an hour, filtered, and there are added 20 grms. Witte's peptone, 20 grms. nutrose, 10 grms. sodium chloride; the mixture is then boiled for an hour, 60 grms. finest agar are added, and it is placed in the autoclave till melted (usually one hour); it is then rendered slightly alkaline to litmus, filtered, and boiled for half an hour. (*b*) 260 c.c.

Kubel-Tiemann litmus[1] solution is boiled for ten minutes, 30 grms. lactose (chemically pure) are added, and the mixture is boiled for fifteen minutes; (*a*) and (*b*) are then mixed hot, well shaken, and, if necessary, the slightly alkaline reaction restored. There are then added 4 c.c. of a 10 per cent. sterile solution of water-free sodium carbonate and 20 c.c. of a freshly prepared solution made by dissolving ·1 gramme crystal violet B, Hoechst, in 100 c.c. hot sterile distilled water. This is the finished medium, and great care must be taken not to overheat it or to heat it too long, as changes in the lactose may be originated. It is convenient to distribute the medium in 80 c.c. flasks.

The principle of the medium is that while there is a food supply very favourable to the b. typhosus and the b. coli, the antiseptic action of the crystal-violet tends to inhibit the growth of other bacteria likely to occur in material which has been subjected to intestinal contamination. In examining fæces, a little is rubbed up in from ten to twenty times its volume of sterile bouillon (a properly made emulsion should just be short of being opaque); in the case of urine or water, the fluid is centrifugalised and the deposit or lower portion is used for the inoculation procedures.

For use the medium is distributed in Petri capsules in a rather thicker layer than is customary in an ordinary plate. This sheet of medium must be transparent, but must not be less than 2 mm. in thickness—in fact, ought to be about 4 mm. After being poured, the capsules are left with the covers off for an hour or so, to allow the superficial layers of the medium to become set hard. The effect of this is that during incubation no water of condensation forms on the lid of the capsule, and thus the danger of this fluid dropping on to the developing colonies is avoided. The antiseptic nature of the crystal-violet is sufficient to prevent the growth of any aerial organisms falling on the agar during its exposure to the air. The plates are usually inoculated by means of a glass spreader made by bending 2 inches of a piece of glass rod at right angles to the rest of the rod. In the case of fæces one or two loopfuls of an emulsion made as described above are placed on the surface of a plate and thoroughly distributed by means of the spreader; when the material is less rich in bacteria the spreader may be dipped in the infective fluid. In either case two or three further plates are successively spread, without any intervening sterilisation of the spreader. The plates are again exposed to the air after inoculation for half an hour, and then incubated for twenty-four hours. At the end of such a period b. coli colonies are 2 to 6 mm. in diameter, stained distinctly red, and are non-transparent. Colonies of the b. typhosus are seldom larger than 2 mm., they are blue or bluish-violet in colour, are glassy and dew-like in character, and have a single contour. Sometimes in the plates b. subtilis and its congeners appear, and colonies of these organisms have a blue colour. Their growth is, however, more exuberant than that of

[1] The litmus solution is made as follows: Solid commercial litmus is digested with pure spirit at 30° C. till on adding fresh alcohol the latter becomes only of a light violet colour. A saturated solution of the residue is then made in distilled water and filtered. When this is diluted with a little distilled water it is of a violet colour, which further dilution turns to a pure blue. To such a blue solution very weak sulphuric acid (made by adding two drops of dilute sulphuric acid to 200 c.c. water) is added till the blue colour is turned to a wine-red. Then the saturated solution of the dye is added till the blue colour returns.

the typhoid bacillus,—being often heaped up in the centre,—and the contour of the colony is often double.

Fawcus's Picric Acid and Brilliant Green Medium.—This is a modification of Conradi's medium which has been used with great success at the Royal Army Medical College in the investigation of typhoid carriers. It is made as follows: To 900 c.c. tap water add 5 grms. sodium taurocholate (which is commercially prepared from ox bile), 30 grms. powdered agar, 30 grms. Witte's peptone, 5 grms. sodium chloride; steam for three hours, clear with white of egg, filter through cotton wool, and bring to a reaction of +15 with normal lactic acid or caustic soda, and sterilise. Dissolve 10 grms. lactose in 100 c.c. sterile distilled water, and add to melted agar. Mix and filter through Chardin paper, sterilise carefully, and store in 100 c.c. flasks. For use, add to each 100 c.c. flask 2 c.c. of a 1–1000 watery solution of brilliant green and 2 c.c. of a 1 per cent. watery solution of picric acid. Pour into large Petri dishes, and leave these to stand inverted at 37° C. till the surface hardens. Inoculate as usual. Colonies of b. typhosus of twenty-four hours' growth are of about 1 mm. in diameter, transparent and refracting; those of b. coli, on the other hand, have a deep green centre, though later typhoid colonies may also present a pale green centre.

Petruschky's Litmus Whey.—The preparation of this medium, which is somewhat difficult, is as follows: Fresh milk is slightly warmed, and sufficient very dilute hydrochloric acid is added to cause precipitation of the casein, which is now filtered off. Dilute sodium carbonate solution is added up to, but not beyond, the point of neutralisation, and the fluid steamed for one to two hours, by which procedure any casein which has been converted into acid albumin by the hydrochloric acid is precipitated. This is filtered off, and a clear, colourless, perfectly neutral fluid should result. Its chief constituent, of course, will be lactose. To this, sufficient Kubel-Tiemann solution of litmus is added, the medium is put into tubes and then sterilised. (This is the original method, but it is better, after the casein has been precipitated, to make the medium slightly alkaline with the sodium carbonate and bring to the boiling-point; then filter, neutralise, add the litmus, and sterilise.) After growth has taken place, the amount of acid formed can be estimated by dropping in standardised soda solution till the tint of an uninoculated tube is reached.

Any one of these media in the hands of a worker accustomed to its use will yield good results. MacConkey's medium is that most used by British workers, and it has the merit of being easily prepared. As the result of a considerable experience we have found it most useful and reliable. Next to it we would place Fawcus's modification of Conradi's brilliant green method.

Browning's Brilliant Green Method.—In this method advantage is taken of the fact that brilliant green has a greater inhibitory effect on b. coli generally than on b. typhosus and the paratyphoid group of bacilli. The amount of the dye necessary to bring about the desired result is not a fixed quantity in each case, as it depends on the number of organisms in the fæces and also on the organic matter. A number of dilutions of the dye are therefore used. Tubes of peptone water (Witte's peptone 2 per cent. and sodium chloride ·5 per cent.), each containing

10 c.c., are prepared. The brilliant green (Bayer's Extra Cryst.) is used as a 1:10,000 solution in distilled water. To a number of tubes of peptone water, say half a dozen, varying amounts of the brilliant green solution—from 0·1 c.c. to 0·7 c.c.—are added in series. Each tube is then inoculated with a loopful of an emulsion of fæces in distilled water and the tubes are incubated at 37° C. for twenty-four hours. At the end of this time a loopful is taken from each tube and strokes are made on plates of MacConkey's medium—three strokes with each loopful. Two plates will be sufficient for the strokes from all the dilutions. After incubation for another twenty-four hours the plates are examined for typhoid colonies; often a pure culture is obtained from one of the dilutions. When the bacilli are scanty the results yielded by the method are remarkable. The method is not suitable for the isolation of dysentery bacilli.

Whilst b. coli generally is inhibited by the brilliant green, Browning and his co-workers have found that some strains, especially the inosite-fermenters, *e.g.*, b. lactis aerogenes, are equally resistant with b. typhosus, but, on the other hand, are much less resistant to telluric acid. They therefore recommend that 0·33 c.c. of a 1 : 1000 solution of telluric acid be added to the tubes of peptone water along with the varying amounts of brilliant green.

Whilst a number of tubes, as above described, are essential for the best results, a one-tube method may often be used with success. In this case 0·5 c.c. of the 1 : 10,000 solution of brilliant green is the optimum quantity. This is specially successful with paratyphoid B.

Methods have also been devised, on the same principle as the above, for inhibiting the growth of various organisms present along with b. diphtheriæ, and thus aiding the isolation of the latter. We give the following:—

Conradi and Troch's Method for isolating the B. Diphtheriæ.—This medium is made by mixing 1000 c.c. water, 10 grms. Lemco, 5 grms. sodium chloride, 20 grms. Witte's peptone, and 6 grms. calcium bimalicum, steaming for half an hour and filtering. To this slightly acid fluid 1 per cent. of glucose is added and one part is mixed with three parts fresh ox serum. To each 100 c.c. of the bouillon-serum medium 2 c.c. of a 1 per cent. solution of potassium telluricum is added. The finished medium is distributed in Petri capsules and coagulated by a quarter of an hour's exposure to 85° C. A tube of ordinary Löffler's serum is inoculated with the material to be examined for the diphtheria bacillus and incubated for three hours. The surface is then scraped and two plates of the special medium are inoculated, and incubated for twenty hours. Any diphtheria colonies present are a deep black from a reduction of the dioxide of tellurium; pseudo-diphtheria colonies show yellow-grey or greyish-black.

Smith's Method.—The following medium, containing telluric acid, has been devised by J. F. Smith; it gives excellent results. It has the composition:—

Peptone-water agar (neutral to litmus) . . .	100	c.c.
Sheep's serum (sterilised at 57° C.) . . .	5	,,
1 per cent. telluric acid solution in distilled water	0·9	,,

The serum is added to the melted agar at a temperature of 50° C. On this

medium the diphtheria bacillus forms large white colonies after incubation for twenty-four hours. The growth of many organisms is inhibited.

Media for growing Trichophyta, Moulds, etc.

1. *Beer Wort Agar.*—Take beer wort as obtainable from the brewery and dilute it till it has an s.g. of 1100. Add 1·5 per cent. of powdered agar, and heat in the Koch till it is dissolved (usually about two hours are necessary). Filter rapidly and fill into tubes. Sterilise in the Koch for twenty minutes on three successive days. If the medium is heated too long it loses the capacity of solidifying.

2. *Sabouraud's Media.*—Sabouraud recommends the following media, the first being that most frequently used :—

(1)	Pure tap water	1000 c.c.
	Maltose ("brute de Chanut") . . .	40 grms.
	Peptone ("granulée de Chassaing") . .	10 ,,
	Agar	18 ,,
(2)	Pure tap water	1000 c.c.
	Glucose ("massée de Chanut") . . .	40 grms.
	Peptone ("granulée de Chassaing") . .	10 ,,
	Agar	18 ,,

In order to secure uniformity of results over as long a series of observations as possible, it is advisable to make up these media in large quantities, say three litres at a time in a five-litre flask. The agar is put to soak in the water for an hour, the other ingredients are added and dissolved by gradually heating to 120° C. in an autoclave. The medium is then thoroughly mixed by stirring and rapidly filtered through *papier Chardin* (Cogit, 36 Boulevard Saint Michel, Paris). For this purpose, Sabourand recommends that ten 500 c.c. flasks should be fitted with funnels and filtration simultaneously carried on in the whole series ; whenever in any one of the flasks the filtrate begins to pass only in drops, a new filter paper is substituted. In this way the three litres of medium can be filtered in a few minutes. We have found that the procedure can be simplified without apparently affecting the efficiency of the medium, by dissolving the agar and sugar in one flask, and the peptone in another. The contents of each are filtered and the two filtrates are then mixed ; in this procedure only two or three filter papers are required for the rapid filtration of a large quantity of the agar and sugar moiety. If filtration in a number of flasks is practised, the contents of all are mixed and then distributed in $6 \times \frac{5}{8}$ inch test-tubes (plugged with non-absorbent cotton) and sterilised by one exposure in the autoclave at 120° C.—the temperature being very gradually raised. These tubes are used for the primary inoculations, and during incubation, which is necessarily prolonged and usually carried out at 22° C., should be placed in a covered glass jar the lid of which is kept slightly raised at one side with a pad of wool to permit the access of a certain amount of air,—by this device undue drying of the medium is at the same time prevented ; the inoculated tubes should not be covered with rubber caps. The study of the characters of the large colonies of trichophyta, etc., is best carried out with media distributed in 250 or even 500 c.c. Erlenmyer flasks in which the requisite surface of medium with a suitably moist atmosphere is obtained.

The Use of the Ordinary Culture Media.

The culture of bacteria is usually carried on in test-tubes conveniently $6 \times \frac{5}{8}$ in., but for many purposes smaller tubes, $5 \times \frac{1}{2}$ in., are equally suitable and medium is thus saved. The tubes ought to be very thoroughly washed and dripped, and their mouths plugged with plain cotton wool. They are then sterilised for one hour at 170° C. If the tubes be new, the glass, being usually packed in straw, may be contaminated with the extremely resisting spores of the b. subtilis. Cotton-wool plugs are universally used for protecting the sterile contents of flasks and tubes from contamination with the bacteria of the air. A medium thus protected will remain sterile for years. Whenever a protecting plug is removed for even a short time, the sterility of the contents may be endangered. It is well to place the bouillon, gelatin, and agar media in the test-tubes directly after filtration. The media can then be sterilised in the test-tubes.

In filling tubes, care must be taken to run the liquid down the centre, so that none of it drops on the inside of the upper part of the tube with which the cotton-wool plug will be in contact, otherwise the latter will subsequently stick to the glass and its removal will be difficult. In the case of liquid media, test-tubes are filled about one-third full. With the solid media the amount varies. In the case of gelatin media, tubes filled one-third full and allowed to solidify while standing upright, are those commonly used. With organisms needing an abundant supply of oxygen the best growth takes place on the surface of the medium, and for practical purposes the surface ought thus to be as large as possible. To this end "sloped" agar and gelatin tubes are used. To prepare these, tubes are filled only about one-sixth full, and after sterilisation are allowed to solidify lying on their sides with their necks supported so that the contents extend 3 to 4 inches up, giving an oblique surface after solidification. Thus agar is commonly used in such tubes (less frequently gelatin is also "sloped"), and this is the position in which blood serum is inspissated. Tubes, especially those of the less commonly used media, should be placed in large jars provided with stoppers, otherwise the contents are apt to evaporate. A tube of medium which has been inoculated with a bacterium, and on which growth has taken place, is called a "culture." A "pure culture" is one in which only one species is present. The methods of obtaining pure cultures will presently be described. When a fresh tube of medium is inoculated from an already existing

culture, the resulting growth is said to be a "sub-culture" of the first. Manipulations involving the transference of small portions of growth either from one medium to another, as in the inoculation of tubes, or, as will be seen later, to cover-glasses for microscopic examination, are effected by pieces of platinum wire (Nos. 24 or 27 Birmingham wire gauge—the former being the thicker) fixed in glass rods 8 inches long.[1] If platinum wire is

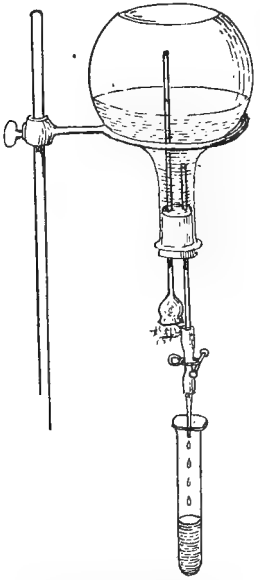

FIG. 11.—Apparatus which may be used for filling tubes. The apparatus explains itself. The indiarubber stopper with its tubes ought to be sterilised before use.

c. "Deep" tube for cultures of anaerobes.

not available an excellent substitute,—especially for students' work,—is found in "resistance wire," No. 25 B.W.G. This is best mounted in an aluminium handle. Every worker should have three wires. Two are $2\frac{1}{2}$ inches long, one of these being straight (Fig. 13, *a*), and the other having a loop turned upon it

[1] Aluminium rods are made which are very convenient. The end is split with a knife, the platinum wire is inserted and fixed by pinching the aluminium on it in a vice.

(Fig. 13, *b*). The latter is referred to as the platinum "loop" or platinum "eyelet," and is used for many purposes. "Taking a loopful" is a phrase constantly used. The third wire (Fig. 13, *c*) ought to be 4½ inches long and straight. It is used for making anaerobic cultures. It is also very useful to have at hand a platinum-iridium spud. This consists of a piece of platinum-iridium about 1½ inch long, 2 mm. broad, and of sufficient thickness to give it a firm consistence; its distal end is expanded into a diamond shape, and its proximal is screwed into an aluminium rod. It is very useful for making scrapings from organs and for disintegrating felted bacterial cultures; in

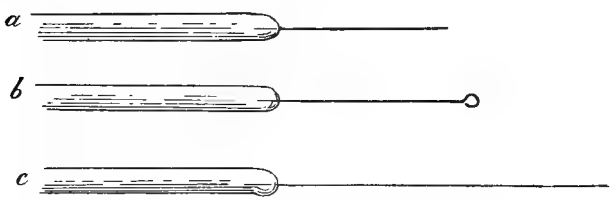

FIG. 13.—Platinum wires in glass handles.
a. Straight needle for ordinary puncture inoculations. *b*. Platinum "loop." *c*. Long needle for inoculating "deep" tubes.

such manipulations the ordinary platinum wire is awkward to work with, as it bends so easily.

If a platinum wire heavily charged with bacteria be sterilised in a Bunsen flame it may "spark" and unkilled bacteria may thus fall on the worker's bench. In working with organisms highly pathogenic to man, *e.g.*, glanders, plague, Malta fever, it is well to substitute for platinum needles glass rods drawn out to capillary diameter, each of which can be destroyed after use. These before use are sterilised by passing through the flame, and when contaminated are dropped into a 1–1000 solution of corrosive sublimate instead of being heated.

Cultures on a solid medium are referred to (1) as "puncture" or "stab" cultures, or (2) as "stroke" or "slant" cultures, according as they are made (1) on tubes solidified in the upright position, or (2) on sloped tubes.

To inoculate, say, one ordinary upright gelatin tube from another, the two tubes are held in an inverted position between the forefinger and thumb of the left hand with their mouths towards the person holding them; the plugs are twisted round once or twice, to make sure they are not adhering to the glass. The short, straight platinum wire is then heated to redness from

point to insertion, and 2 to 3 inches of the glass rod are also passed two or three times through the Bunsen flame. It is held between the right fore and middle fingers, with the needle projecting backwards, *i.e.*, away from the right palm. Remove plug from culture tube with right forefinger and thumb, and continue to hold it between the same fingers by the part which projected beyond the mouth of the tube. Now touch the culture with the platinum needle, and, withdrawing it, replace plug. In the same way remove plug from tube to be inoculated, and plunge platinum wire down the centre of the gelatin to within half an inch of the bottom. It must on no account touch the glass above the medium. The wire is then immediately sterilised. A variation in detail of this method is to hold the plug of the tube next the thumb between the fore and middle fingers, and the plug of the other between the middle and ring fingers, then to make the inoculation (Fig. 14). If a tube contain a liquid medium, it must be held in a sloping position between the same fingers, as above. For a stroke culture the platinum loop is used, and a little of the culture is smeared in a line along the surface of the medium from below upwards. In inoculating tubes, it is always well, on removing the plugs, to make sure that no strands of cotton fibre are adhering to the inside of the necks. As these might be touched with the charged needle and the plug thus be contaminated, they must be removed by heating the inoculating needle red-hot and scorching them off with it. When the platinum wires are not in use they may be laid in a rack made by bending up the ends of a piece of tin, as in

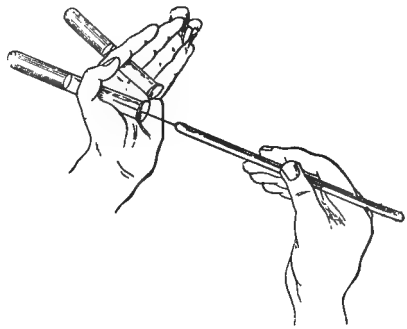

FIG. 14.—Another method of inoculating solid tubes.

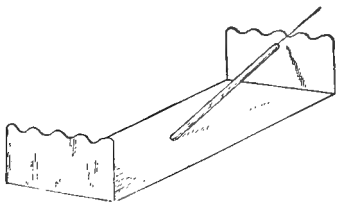

FIG. 15.—Rack for platinum needles.

Fig. 15. If the top of a plug be dusty it is best to singe it before extraction.

The Methods of the Separation of Aerobic Organisms. Plate Cultures.

The general principle underlying the methods of separation is the distribution of the bacteria in or on one of the solid media so that the colonies formed by the individual organisms are sufficiently far apart to allow their being examined separately. For the purpose, circular shallow glass capsules, each fitted with an overlapping glass cover, are almost universally used; these are known as Petri dishes or capsules. The medium, after being melted, is poured into a sterile capsule and allowed to solidify, so as to form a thin layer; in this way the colonies which afterwards grow are readily accessible. In one method the material containing the bacteria is smeared over the surface of the medium after it has solidified in the capsule,—"smear method." In another method the organisms are mixed with the medium when in the melted state, and the mixture is then poured into the capsule and allowed to solidify,—"dilution method." The former gives the best results in the case of most pathogenic organisms.

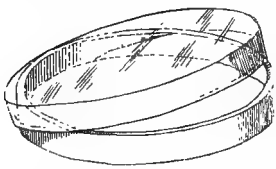

Fig. 16.—Petri's capsule. (Cover shown partially raised.)

The smear method is the more convenient, and is that used for the separation of typhoid and dysentery bacilli, meningococci, etc.; it is, in fact, capable of almost universal application. The procedure varies according to the material to be examined. If the organisms are on a swab, say from the naso-pharynx, consecutive strokes are made all over the surface of the medium, always the same portion of the swab being brought into contact with it. In this way the organisms are gradually wiped off the swab, till in the later strokes they may be deposited at sufficiently wide intervals to give separate colonies. Sometimes it is advisable to smear two plates consecutively with the same portion of the swab. If the material to be examined is fluid, *e.g.*, an emulsion of fæces, the usual method is to place a loopful on the surface of the medium, and then, with a sterile glass-rod bent at a right angle, to smear the whole surface. If the organisms are found, on microscopic examination, to be very numerous, say in pus, it will be advisable to dilute with sterile saline before

making the smears. The characters of the colonies which appear on the plates can be examined with a hand-lens, magnifying about 6 diameters. In some cases examination under a low-power of the microscope is an advantage; the plate in the inverted position can be put on the stage of the microscope for this purpose. For the culture of special organisms, as afterwards detailed, the agar or other medium is smeared with sterile serum or blood according to the growth requirements of the organism, or the serum or agar is added before the medium is poured.

The principle just described may be applied also to agar in tubes, but the results generally are not so satisfactory, and the characters of the colonies cannot be so readily studied. In this case two or three agar tubes are taken, a platinum loop is charged with the material to be examined, and a series of undulating strokes is made from below upwards on the surface of the agar, one tube after the other being used without recharging the needle. The tubes after inoculation should be kept in the upright position, so that the water of condensation is not allowed to run over the surface.

In the second method, which we have called the "dilution method," the bacteria are added to the medium when liquid, and mixed by careful shaking; the inoculated medium is then poured out into a capsule and allowed to solidify. As in this case the organisms are diffused throughout the medium, some of the colonies grow on the surface of the medium—"superficial colonies"—others in its substance—"deep colonies." These often show different appearances, which are sometimes used in the systematic description of an organism. As the bacteria may produce far too many colonies to allow separation, means must also be used for making different dilutions, a separate plate being prepared for each. If gelatine is used, the medium in tubes is melted and kept in a beaker of water at about 28° C. If agar is used, the medium is melted thoroughly by boiling in a vessel of water and then allowed to cool to about 43° C., at which temperature the inoculations are made. The following are the details:—

The contents of three tubes, marked *a*, *b*, *c*,[1] are liquefied as above described. Inoculate *a* with the bacterial mixture. The amount of the latter to be taken varies, and can only be regulated by experience. If the microscope shows enormous numbers of different kinds of bacteria present, just as much as adheres to the point of a straight platinum needle is sufficient. If the number of bacilli is small, one to three loops

[1] For marking glass vessels it is convenient to use the red, blue, or yellow oil pencils specially made for the purpose.

of the mixture may be transferred to the medium. Shake *a* well, but not so as to cause many fine air-bubbles to form. Transfer two loops of medium from *a* to *b*. Shake *b* and transfer five loops to *c*. The plugs of the tubes are in each case replaced and the tubes returned to the beaker. The contents of the three tubes are then poured out into three capsules. In doing so the plug of each tube is removed and the mouth of the tube passed two or three times through the Bunsen flame, the tube being meantime rotated round a longitudinal axis. Any organisms on its rim are thus killed. The capsules are labelled and set aside till growth takes place.

For accurate work it will be found convenient to carry out the dilutions in definite proportions. The following is the procedure which we have found very serviceable: In a number of small sterile test-tubes ·95 c.c. sterile water is put. To the first tube we add ·05 c.c. of the bacterial mixture. The contents of the tube are well shaken up, and the pipette is sterilised by being washed out with boiling water. It is allowed to cool, and ·05 c.c. of fluid is transferred from the first tube to the second. By a similar procedure ·05 c.c. is transferred from the second to the third, and so on. There is thus effected a twenty-fold dilution in each successive tube. After these steps have been carried out, a definite amount, say ·05 c.c., is transferred from each tube to a tube of melted medium,—the medium being afterwards plated and the colonies counted when growth occurs. The number of tubes required will vary according to the number of bacteria in the original mixture, but usually four or five will be sufficient.

Enumeration of Colonies.—The dilution method just described supplies the means of counting the number of living bacteria in a fluid, the proviso being always made that they are capable of growth in the medium used. For pathogenic organisms one of the agar media is generally used, whilst in the case of water, gelatine is most suitable. The dilutions are made by the quantitative method, and a given amount, say ·1 c.c., is taken from one of the dilutions and transferred to a tube of melted medium, and, after gentle mixing, the medium is poured in a Petri capsule. It is advisable to take samples in this way from two or even three of the dilutions. To aid the counting of the colonies which develop, various patterns of ruled glass plates have been introduced. If the ruling is in the form of squares of given size, the number of colonies in several squares is counted, and as the area of the Petri dish can be got by multiplying the square of its radius by $3\frac{1}{7}$, the whole number can then be calculated. Petri dishes are rarely flat, and unequal distribution of the colonies has accordingly to be taken into account. The dilution to be selected for taking the sample for plating will depend upon the relative abundance of the organisms in the original fluid.

Separation of Pathogenic Bacteria by Inoculation of Animals.—It is found difficult, and often impossible, to separate

by ordinary plate methods certain pathogenic organisms, such as b. tuberculosis, b. mallei, and the pneumococcus, when such occur in conjunction with other bacteria. These grow best on special media, and the first two grow so slowly that the other organisms present may outgrow them, cover the whole plates, and make separation difficult. The method adopted in such cases is to inoculate an animal with the mixture of bacilli, wait until the particular disease develops, kill the animal, and with all aseptic precautions (*vide* p. 140) inoculate tubes of suitable media from characteristic lesions situated away from the seat of inoculation, *e.g.*, from spleen in the case of b. tuberculosis, spleen or liver in the case of b. mallei, and heart blood in the case of pneumococcus.

Separation by killing Non-spored Forms by Heat.—This is a method which has a limited application. As has been said, the spores of a bacterium resist heat more than the vegetative forms. When a mixture contains spores of one bacterium and vegetative forms of this and other bacteria, then if the mixture be heated for 10 minutes at 80° C. all the vegetative forms may be killed, while the spores will remain alive and will develop subsequently. Several tubes of different media should be inoculated and treated thus, as the success of the method is very variable. The method is also often used to aid in the separation of b. tetani, *vide infra*.

The Principles of the Culture of Anaerobic Organisms.

All ordinary media, after preparation, may contain traces of free oxygen, and will absorb more from the air on standing. (1) For the growth of anaerobes this oxygen may be expelled by the prolonged passing of an inert gas, such as hydrogen, through the medium (liquefied if necessary). Further, the medium must be kept in an atmosphere of the same gas while growth is going on. (2) Media for anaerobes may be kept in contact with the air, if they contain a reducing agent which does not interfere with bacterial growth. Such an agent takes up any oxygen which may already be in the medium, and prevents further absorption. The reducing body used is generally glucose, though formate of sodium may be similarly employed. The preparation of such media has already been described (pp. 36, 38). In this case the medium ought to be of considerable thickness.

The Supply of Hydrogen for Anaerobic Cultures.—The gas is generated in a large Kipp's apparatus from pure sulphuric acid and pure zinc. It

is passed through three wash-bottles, as in Fig. 17. In the first is placed a solution of lead acetate (1 in 10 of water) to remove any traces of sulphuretted hydrogen. In the second is placed a 1 in 10 solution of silver nitrate to remove any arseniuretted hydrogen which may be present if the zinc is not quite pure. In the third is a 10 per cent. solution of pyrogallic acid in caustic potash solution (1 : 10) to remove any traces of oxygen. The tube leading from the last bottle to the vessel containing the medium ought to be sterilised by passing through a Bunsen flame, and should have a small plug of cotton wool in it to filter the hydrogen germ-free.

Commercial hydrogen as sold in cylinders may be used, but this must be purified as above.

Pyrogallate of Potassium for Anaerobic Cultures. -In arranging for the

absorption of oxygen by this substance the proportions used in Bulloch's separation method (below) may be employed. Here 109 grms. solid caustic potash are dissolved in 145 c.c. water, and to this 2 4 grms. pyrogallol are added.

Bulloch's Apparatus for Anaerobic Culture.—This can be recommended for plating out mixtures containing anaerobes, and for obtaining growths (especially surface growths) of the latter. It consists (Fig. 18) of a glass plate as base on which a bell-jar can be firmly luted down with unguentum resinæ. In the upper part of the bell-jar are two apertures furnished with ground stoppers, and through each of the latter passes a glass tube on which is a stop-cock. One tube, bent slightly just after passing through the stopper, extends nearly to the bottom of

the chamber; the other terminates immediately below the stopper. In using the apparatus there is set on the base-plate a shallow dish, of slightly less diameter than that of the bell-jar, and having a little heap of from 2 to 4 grms. of dry pyrogallic acid placed in it towards one side. Culture plates, which should be of rather greater thickness than for ordinary aerobic work, can be stacked on a frame of glass rods resting on the edges of the dish, or a beaker containing culture tubes can be placed in it. The bell-jar is then placed in position so that the longer glass tube is situated over that part of the bottom of the shallow dish farthest away from the pyrogallic acid, and the bottom and stoppers are luted. The air in the bell-jar is now expelled by passing a current of hydrogen through the short glass tube, and both stoppers are closed. A partial vacuum is then effected in the jar by connecting up the short tube with an air-pump, opening the tap, and giving a few strokes of the pump. A solution of 109 grms. solid caustic potash dissolved in 145 c.c. water is made, and into the vessel containing it a rubber tube connected with the long glass tube is made to dip, and the stopper of the latter being opened, the fluid is forced into the chamber and spreads over the bottom of the shallow dish; potassium pyrogallate is thus formed, which absorbs any free oxygen still present. Before the whole of the fluid is forced in, the rubber tube is placed in a little boiled water, and this, passing through the glass tubes, washes out the potash and prevents erosion of the glass. The whole apparatus may be placed in the incubator till growth occurs.

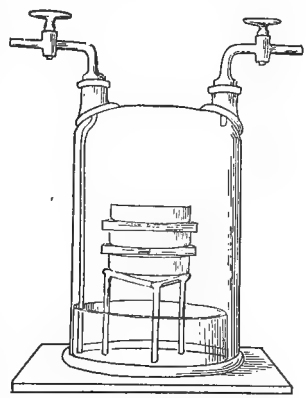

FIG. 18.—Bulloch's apparatus for anaerobic plate cultures.

M'Intosh and Fildes Anaerobic Jar.—These authors have designed a jar in which tubes may be incubated under anaerobic conditions, the oxygen being absorbed by spongy palladium. A glass pickle jar, fitted with a metal lid screwing down on a rubber washer, is employed. Into a hole in this lid there is soldered a small stopcock such as is used in model steam-engines. A bracket of sheet brass, carrying a capsule of fine brass or copper gauze, is fixed to the inner end of the stopcock by means of the screw-on collar of the latter (Fig. 19). 0·25 gr. fine asbestos wool is placed in a porcelain capsule and soaked in 1·5 c.c. 10 per cent.

palladium chloride (to which a little hydrochloric acid may be added if necessary), moulded into a flat cake and slowly dried. The palladium chloride is reduced by heating the dried wool pledget in a smoky gas flame till it is coated with carbon and then burning in a blowpipe. The wool is then folded into the gauze capsule, which should be of just sufficient size to enclose it. The lid being thus prepared, the culture tubes are placed in the bottle. The capsule is heated in a Bunsen, and the lid, with the tap closed, is rapidly fixed on the jar. The tap is opened and a piece of pressure tubing leading from a hydrogen generator is connected with it. The hydrogen is turned on, and combines with the oxygen in the vessel till no free oxygen remains. At the end of the process the internal pressure prevents the further entry of hydrogen. The jar is allowed to cool, the tap shut off and disconnected from the hydrogen supply, and the apparatus can then be incubated. It is absolutely necessary that the lid of the jar should be airtight. This can be tested by placing a few drops of ether in the jar, fixing on the

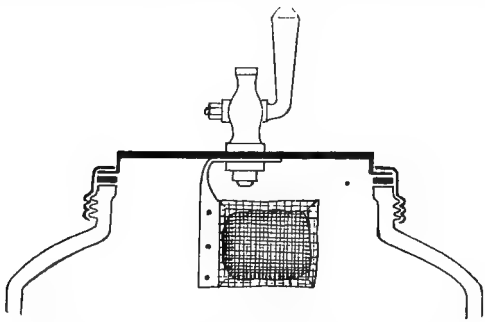

FIG. 19.—Lid of M'Intosh and Fildes anaerobic jar.[1]

lid, and plunging the vessel in hot water; any leak can thereby be detected. A fitting similar to above can be adapted to any tin vessel with a "lever-off" lid. In this case the lid is luted on with plasticine.

Lentz's Method.—The requisites for this are glass plates, discs composed of layers of filter paper compressed together and impregnated with pyrogallol, some circular glass dishes of the form of the halves of a Petri capsule. Plate cultures are prepared in the glass dishes in the usual way and the medium is allowed to solidify. A disc is placed on a glass plate and moistened with a potassium hydrate solution; a dish is then rapidly inverted over it and luted on the glass plate with plasticine. The other dishes are treated in a similar way.

M'Leod has modified this method in the following way. Instead of glass plates he uses shallow circular porcelain capsules[2] (Fig. 20) which are covered in by a porcelain diaphragm with the exception of a circular

[1] For the use of this figure we are indebted to the National Insurance Medical Research Committee, in whose Special Report, No. 12 (1917), the apparatus is described.

[2] The capsules may be obtained from Messrs. Thomson, Skinner, & Hamilton, Glasgow.

opening in the middle. The interior of each capsule is divided into two halves by a partition which, however, does not extend the whole way up; in one half, solution of pyrogallic acid is placed, in the other, solution of potassium hydrate. Plasticine is placed round the margin of the upper surface of each capsule. Plate cultures having been made in glass dishes in the usual way, each dish is inverted and placed over a porcelain capsule and carefully fixed in the plasticine. When this has been done, the two fluids in the capsule are mixed by tilting and the oxygen in the

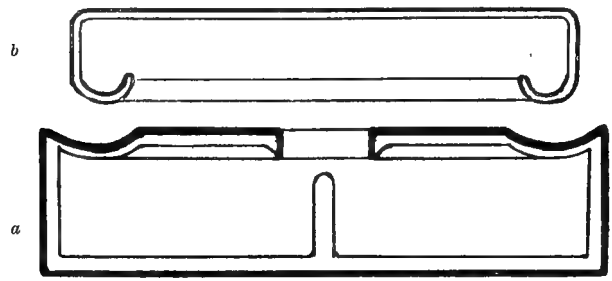

FIG. 20.—M'Leod's capsule for anaerobic plating, shown in section.

interior is rapidly absorbed. Another improvement is that the edges of the glass dishes which rest in the plasticine are turned up so as to prevent the condensation water from running over the plasticine (Fig. 20, *b*).

Henry's Method.—In this modification two shallow circular dishes (portions of Petri capsules) are separated by a tin diaphragm, in the centre of which is an aperture (Fig. 21). The upper dish contains the plate culture, the lower (smaller) contains pyrogallic crystals. Grooves are present in the metal to receive the margins of the dishes, which are fixed in with plasticine. The lower dish is first fixed in position, and

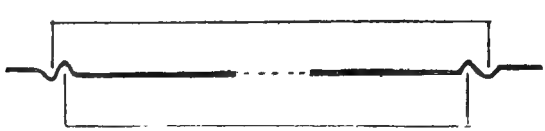

FIG. 21.—Henry's apparatus.

just before the upper dish is adjusted, 10 c.c. of caustic potash are run into the lower through the opening in the plate.

It is often advisable in dealing with material suspected to contain anaerobes to inoculate an ordinary deep glucose agar tube with it, and, incubating for 24 or 48 hours, to then apply an anaerobic separation method to the resultant growth. Sometimes the high powers of resistance of spores to heat may be taken advantage of in aiding the separation (*vide* Tetanus).

Cultures of Anaerobes.—When by one or other of the above

methods separate colonies have been obtained, growth may be maintained on media in contact with ordinary air. The media generally used are those which contain reducing agents, and the test-tubes containing the medium must be filled to a depth of 4 inches. They are sterilised as usual, and are called "deep" tubes (Fig. 12, *c*). The long straight platinum wire is used for inoculating, and it is plunged well down into the "deep" tube. A little air gets into the upper part of the needle track, and no growth takes place there, but in the lower part of the needle track growth occurs. From such "deep" cultures growths may be maintained indefinitely by successive sub-cultures in similar tubes. Even ordinary gelatin and agar can be used in the same way if the medium is heated to boiling-point before use to expel any absorbed oxygen.

Carroll's Method for Anaerobic Cultures.—This may be used with culture tubes containing any of the media suitable for anaerobes and also for surface growths on sloped tubes. There are required a dry tube of the same diameter as the culture tube, a short U-shaped glass tube, and two pieces of rubber tubing all of like diameter. The culture tube having been inoculated, the plug is pushed home below the lip of the tube. The ends of the U-tube are smeared with vaseline and a rubber tube slipped over each; the end of the culture tube being similarly treated, the free end of one of the rubber tubes is pushed over it till the glass of the U-tube is in contact with the glass of the culture tube. In the dry tube 1 or 2 grms. of pyrogallic acid are placed, and the powder is packed down with a layer of filter paper. Ten or twenty cubic centimetres of a 10 per cent. solution of sodium hydrate are then poured in, and the tube is quickly connected up by the rubber tubing with the other end of the U-tube. In this apparatus the oxygen is absorbed by the sodium pyrogallate, and the conditions for anaerobic growth are fulfilled.

Buchner's Anaerobic Tube.—This may be used either for maintaining surface growths of anaerobes or for keeping free from oxygen sloped culture media which are being used for separating anaerobes from mixtures. Dry pyrogallol is placed in a cylindrical jar of diameter sufficient to contain the tube or tubes of media. The tubes are then inserted, potassium hydrate solution (p. 62) is poured into the jar, and its mouth quickly stoppered with a rubber or glass stopper. The stopper is made airtight by sealing with paraffin. The pyrogallol absorbs the oxygen in the jar, and thus the cultures are kept in oxygen-free surroundings.

Cultures of Anaerobes in Liquid Media.—It is necessary to employ such in order to obtain the toxic products of the growth of anaerobes. Glucose broth is usually most convenient. It is placed either (1) in a conical flask with a lateral opening and a perforated indiarubber stopper, through which a bent glass tube passes (as in Fig. 22 *a*), by which hydrogen may be delivered, or (2) in a conical flask with a rubber stopper furnished with two holes (as in Fig. 22, *b*), through a tube in one of which hydrogen is delivered, while through the tube in the other the gas escapes. The inner end of the gas delivery tube must in either case be below the surface of liquid; the inner end of the lateral nozzle in the one case, and the inner end of the

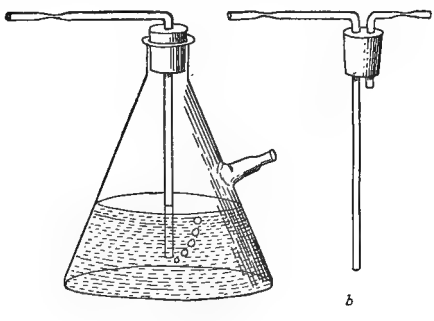

FIG. 22.

a. Flask for anaerobes in liquid media. Lateral nozzle and stopper fitted for hydrogen supply. *b*. A stopper arranged for a flask without lateral nozzle.

escape tube in the other, must of course be above the surface of the liquid. The single tube in the one case and the two tubes in the other ought to be partially drawn out in a flame to facilitate subsequent complete sealing. The ends of the tubes through which the gas is to pass are previously protected by pieces of cotton wool tied on them. It is well also to place in the tube, through which the hydrogen is to be delivered, a little plug of cotton wool. The flask being thus prepared, it is sterilised by methods B (2) or B (3). On cooling it is ready for inoculation. In the case of the flask with the lateral nozzle, the cotton-wool covering having been momentarily removed, a wire charged with the organism is passed down to the bouillon. In the other kind of flask the stopper must be removed for an instant to admit the wire. (In the case of many anaerobes it

is advisable to practise a massive inoculation by pouring into medium part of an actively growing bouillon culture.) The flask is then connected with the hydrogen apparatus by means of a short piece of sterile indiarubber tubing, and hydrogen is passed through for half an hour. In the case of flask (1), the lateral nozzle is plugged with melted paraffin and covered with alternate layers of cotton wool and paraffin, the whole being tightly bound on with string. The entrance tube is now completely drawn off in the flame before being disconnected from the hydrogen apparatus. In the case of flask (2), first the exit tube and then the entrance tube are sealed off in the flame before the flask is disconnected from the hydrogen apparatus. It is well in the case of both flasks to run some melted paraffin all over the rubber stopper. Sometimes much gas is evolved by anaerobes, and in dealing with an organism where this will occur, provision must be made for its escape. This is conveniently done by leading down the exit tube, and letting the end just dip into a trough of mercury (Fig. 23), or into mercury in a little bottle tied on to the end of the exit tube. The pressure of gas within causes an escape at the mercury contact, which at the same time acts as an efficient valve. The method of culture in fluid media is used to obtain the soluble products of such anaerobes as the tetanus bacillus.

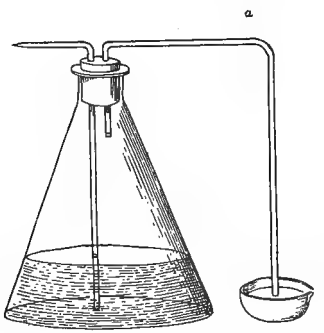

FIG. 23.—Flask arranged for culture of anaerobes which develop gas.
b is a trough of mercury into which exit tube dips.

The Method of Tarozzi.—This observer has found that if small pieces of fresh sterile organs are added to ordinary bouillon, growth of anaerobes takes place under ordinary atmospheric conditions. For this purpose, portions of liver, spleen, or kidney are most suitable. The method has been used in the cultivation of spirochætes, organism of poliomyelitis, etc. It has been shown by Douglas, Fleming, and Colebrook that the addition of pieces of vegetable (even after being boiled), bran, and even asbestos wool, is effective in making a fluid medium suitable for the growth of anaerobes, the presence of fine interstices in the material being an important factor in aiding the growth. It

has not yet been determined whether this is the whole explanation of Tarozzi's method.

When it is desired to grow anaerobes on the surface of a solid medium such as agar, tubes of the form shown in Fig. 24, *a* and *b*, may be used. A stroke culture having been made, the

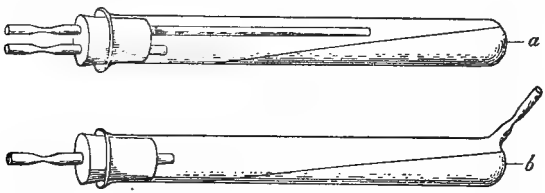

FIG. 24.—Tubes for anaerobic cultures on the surface of solid media.

air is replaced by hydrogen as just described, and the tubes are fused at the constrictions. Such a method is of great value when it is required to get the bacteria free from admixture of medium, as in the case of staining flagella.

MISCELLANEOUS METHODS.

Hanging-drop Cultures.—It is often necessary to observe micro-organisms alive, either to watch the method and rate of their multiplication, or to investigate whether or not they are motile. This is effected by making hanging-drop cultures. The method in the form to be described is only suitable for aerobes. For this special slides are used. Two forms are in use, and are shown in Fig. 25. In *A* there is ground out on one surface a hollow having a diameter of about half an inch. That shown in *B* explains itself. The slide to be used and a cover-glass are sterilised by hot air in a Petri's dish, or simply by being heated in a Bunsen and laid in a sterile Petri to cool. In the case of *A*, one or other of two manipulation methods may be employed. (1) If the organism be growing in a liquid culture, a loop of the liquid is placed on the middle of the under surface of the sterile cover-glass, which is held in forceps, the points of which have been sterilised in a Bunsen flame. If the organism be growing in a solid medium, a loopful of sterile bouillon is placed on the cover-glass in the same position, and a *very* small quantity of the culture (picked up with a platinum needle) is rubbed up in the bouillon. The cover is then carefully lowered over the cell on the slide, the drop not being allowed to touch

the wall or the edge of the cell. The edge of the cover-glass is covered with vaseline, and the preparation is then complete and may be placed under the microscope. If necessary, it may be first incubated and then examined on a warm stage. (2) The sterile cover-glass is placed on a sterile glass plate. The drop is then placed on its *upper* surface, the details being the same as in the last case. The edge of the cell in the slide is then painted with vaseline, and the slide, held with the hollow surface downwards, is lowered on to the cover-glass, to the rim of which it of course adheres. The slide with the cover attached is then quickly turned right side up, and the preparation is complete.

In the case of *B*, the drop of fluid is placed on the centre of

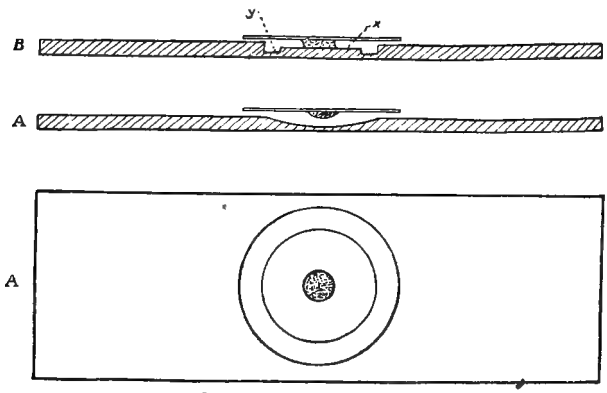

FIG. 25.

A. Hollow-ground slide for hanging-drop cultures, shown in plan and section.
B. Another form of slide for similar cultures.

the table *x*. The drop must be thick enough to come in contact with the cover-glass when the latter is lowered on the slide, and not large enough to run over into the surrounding trench *y*. The cover-glass is then lowered on to the drop, and vaseline is painted along the margin of the cover-glass. It is sometimes convenient for the observation of the growth of bacterial colonies or of fungi to make hanging-drop cultures with a solid medium. This can be done by substituting a drop of melted gelatin or agar for bouillon and inoculating the surface after solidification. The method of microscopic examination is described on page 89.

The Bacteriological Examination of the Blood.—A fairly

large quantity of blood may be obtained by puncture of a vein; this is the only satisfactory method, and should be that followed whenever practicable. The skin over a vein in the forearm or on the dorsum of the foot having been sterilised by being painted with tincture of iodine, the vein is made turgid by pressure, and the needle of a syringe of 10–15 c.c. capacity, sterilised by boiling, is plunged obliquely through the skin by the side of the vessel into the lumen of which the point can then be passed. (If a bandage has been used to make the vein turgid, pressure should be maintained on the puncture, after the needle has been withdrawn, until the bandage has been removed; otherwise a hæmatoma may be formed by leakage from the vessel.) Several cubic centimetres of blood can thus be withdrawn into the syringe. Some of the blood (*e.g.*, 5 c.c.) should be added to small flasks containing 50 c.c. of bouillon; the rest may be used for smearing the surface of agar tubes, or may be added to melted agar at 42° C., which is then plated. The flasks, etc., are then incubated. By this method cultures can often be obtained, especially in severe conditions such as ulcerative endocarditis, streptococcus infection, etc. Part of the blood may be incubated by itself for twenty-four hours and cultures then made. Needless to say, the inoculations of media must be done at the bedside, as of course the blood quickly coagulates in the syringe. Coagulation can be prevented by drawing up into the syringe before it is used a quantity of 2 per cent. sterile sodium citrate equivalent to the amount of blood it is intended to withdraw. Patients who are seriously ill have often a low blood pressure, and difficulties may be experienced due to the collapsed state of the veins. It is important here that the skin surfaces should be as little as possible exposed to cold, which still further diminishes the volume of the superficial circulation. In such cases it may be necessary to expose the vein by dissection.

In examining the blood of the *spleen* a portion of the skin over the organ is sterilised in the same way, a few drops are withdrawn from the organ by a sterile hypodermic syringe, and cultures made. (For microscopic methods, *vide* p. 92.)

Bacteriological Examination of the Cerebro-spinal Fluid —Lumbar Puncture.—This diagnostic procedure, which is often called for in cases of meningitis, can be carried out with a sterilised "antitoxin needle" as follows: The patient should lie on the right side, with knees somewhat drawn up and left shoulder tilted somewhat forward, so that the back is fully exposed. The skin over the lumbar region is then carefully

sterilised with tincture of iodine, and the hands of the operator should be thoroughly purified. The spines of the lumbar vertebræ having been counted, the left thumb or forefinger is pressed into the space between the third and fourth spines in the middle line; the needle is then inserted about half an inch to the right of the middle line at this level and pushed through the tissues, its course being directed slightly inwards and upwards, till it enters the subdural space. When this occurs, fluid passes along the needle, sometimes actually spurting out, and should be received in a sterile test-tube. Several cubic centimetres of fluid can thus usually be obtained, no suction being required; thereafter it can be examined bacteriologically by the usual methods. The depth of the subdural space from the surface varies from a little over an inch in children to 3 inches, or even more, in adults—the length of the needle must be suited accordingly. In making the puncture it is convenient to have either a sterile syringe attached, or to have the thick end of the needle covered with a pad of sterile wool, which is of course removed at once when the fluid begins to flow. It is advisable to use the platinum needles which are specially made for the purpose, as a sudden movement of the patient may snap an ordinary steel needle.

The Bacteriological Examination of the Naso-pharynx.—A specimen of pharyngeal mucus may be obtained by means of a swab of cotton wool on the end of a metal wire. The wire ought to be longer than that used in the case of diphtheria and bent near the extremity. A tongue depressor is used, the wire is introduced into the mouth, and passed up behind the soft palate and then brought into contact with the posterior pharyngeal wall. Care must be taken not to touch any part of the mucous membrane of the mouth. The best method, however, is by means of a simple apparatus introduced by West. This consists of a glass tube shaped like a catheter, in the interior of which is a thin wire bearing the swab, the latter being just within the end of the tube. The bend of the tube can be used to depress the tongue, or a depressor may be used, and when the tube is sufficiently introduced it is turned up behind the soft palate and the end of the wire is pressed so as to protrude the swab, which is then brought into contact with the pharyngeal wall. The swab is then drawn back into the tube (as a matter of fact it usually springs back) and the tube is removed from the mouth. We have found the method to be extremely simple and effective. Plates of "trypagar" or other suitable medium should be inoculated at once (this is essential) and placed in

the incubator as quickly as possible, as cold has an injurious effect on the organisms. If the inoculations have been made at some distance from the laboratory, the plates should be carried in an apparatus with a hot-water jacket—a bag containing a hot-water bottle is often sufficient.

The Bacteriological Examination of Urine.—In such an examination care must be taken to prevent the contamination of the urine by extraneous organisms. In the male, specimens withdrawn by a sterile catheter into a sterile vessel are preferable, but it is often sufficient to wash thoroughly the glans penis and the meatus with 1–1000 corrosive sublimate—the lips of the meatus being everted for more thorough cleansing; the urine is then passed into a series of sterile flasks, the first of which is rejected in case contamination has occurred. In the female, after similar precautions as regards external cleansing, the catheter must be used. The latter must be boiled for half an hour, and anointed with olive oil sterilised by half an hour's exposure in a plugged flask to a temperature of 102° C. Here, again, it is well to reject the urine first passed. It is often advisable to allow the urine to stand in a cool place for some hours, to then withdraw the lower portion with a sterile pipette, to centrifugalise this, and to use the urine in the lower parts of the centrifuge tubes for microscopic examination or for culture.

Filtration of Cultures.—For many purposes it is necessary to filter all the organisms from fluids in which they may have been growing. This is done especially in obtaining the soluble toxic products of bacteria. The only filter capable of keeping back such minute bodies as bacteria is that consisting of a tube of unglazed earthenware as introduced by Chamberland. The efficiency of such a filter depends on the fineness of the grain of the clay from which it is made; the finest is the Kitasato filter and the Chamberland "B" pattern; the next finest is the Chamberland "F" pattern, which is quite good enough for ordinary work. The Doulton porcelain filter is also very suitable and efficient. There are several types of filters, differing slightly in detail, all possessing the common principle. Sometimes the fluid is forced through the porcelain tube. In one form, used for obtaining sterile water, the filter consists practically of an ordinary tap screwed into the top of a porcelain tube. Through the latter the fluid is forced, and passes into a chamber formed by a metal cylinder which surrounds the porcelain tube. The fluid escapes by an aperture at the bottom. Such a filter is very suitable for domestic use, or for use in surgical operating-theatres. As

considerable pressure is necessary, it is evident it must be put on a pipe leading directly from the main. Sometimes, when fluids to be filtered are very albuminous, they are forced through a porcelain cylinder by compressed carbonic acid gas. The filtration of albuminous fluids may sometimes be facilitated by keeping them near blood-heat during the process. For ordinary bacteriological work, filters of various kinds are in the market (such as those of Klein and others), but the most generally convenient is that in which the fluid is sucked through the porcelain by exhausting the air in the receptacle into which it is to flow. This is conveniently done by means of a Geissler's water-exhaust pump (Fig. 26, *g*), which must be fixed to a tap leading directly from the main. The connection with the tap must be effected by means of a piece of thick-walled rubber-tubing as short as possible, wired on to tap and pump, and firmly lashed externally with many turns of strong tape. Before lashing with the tape the tube may be strengthened by fixing round it with rubber solution strips of the rubbered canvas used for mending punctures in the outer case of a bicycle tyre. A manometer tube (*b*) and a receptacle (*c*) (the latter to catch any back flow of water from the pump which may accidentally occur) are intercepted between the filter and the

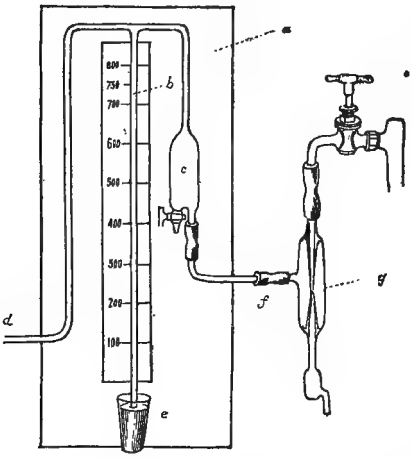

FIG. 26.—Geissler's vacuum pump arranged with manometer for filtering cultures. (The tap and pump are intentionally drawn to a larger scale than the manometer board to show details.)

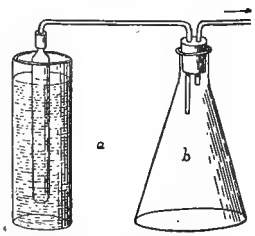

FIG. 27.—Chamberland's candle and flask arranged for filtration.

pump. These are usually arranged on a board *a*, as in Fig. 26. Between the tube *f* and the pump *g*, and between the tube *d* and the filter, it is convenient to insert lengths of flexible lead-tubing connected up at each end with short, stout-walled rubber-tubing.

Filters are arranged in various ways. (*a*) An apparatus is arranged as in Fig. 27. The fluid to be filtered is placed in the cylindrical vessel *a*. Into this a "candle" or "bougie" of porcelain dips. From the upper end of the bougie a glass tube with thick rubber connections, as in Fig. 27, proceeds to flask *b*, and passes through one of the two perforations with which the rubber stopper of the flask is furnished. Through

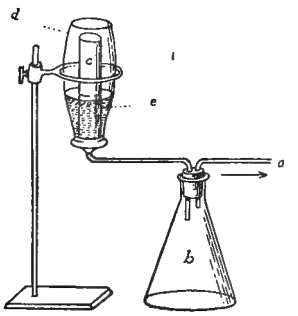

FIG. 28.—Chamberland's bougie arranged with lamp funnel for filtering a small quantity of fluid.

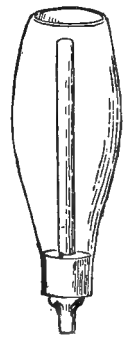

FIG. 29.—Bougie inserted through rubber stopper for same purpose as in Fig. 28.

the other opening a similar tube proceeds to the exhaust-pump. When the latter is put into action the fluid is sucked through the porcelain and passes over into flask *b*. This apparatus is very good, but not suitable for small quantities of fluid.

(*b*) A very good apparatus can be arranged with a lamp funnel and the porcelain bougie. These may be fitted up in two ways. (1) An indiarubber washer is placed round the bougie *c* at its glazed end (*vide* Fig. 28). On this the narrow end of the funnel *d*, which must, of course, be of an appropriate size, rests. A broad band of sheet rubber is then wrapped round the lower end of the funnel and the projecting part of the bougie. It is firmly wired to the funnel above and to the

bougie below. The extreme point of the latter is left exposed, and the whole apparatus, being supported on a stand, is connected by a glass tube with the lateral tube of the flask *b*; the tube *a* is connected with the exhaust-pump. The fluid to be filtered is placed between the funnel and the bougie in the space *e*, and is sucked through into the flask *b*. The efficiency of such a filter, especially when small amounts of fluid are being dealt with, is much increased if when the level of the fluid falls below the upper end of the candle a closely fitting test-tube is slipped over the latter. By this device the leakage of air through the exposed part of the candle is prevented. There are now in the market candles with glass sheaths cemented into a nickle-plated fitting from the lower part of which a metal tube emerges; the latter can be passed through a rubber stopper into a filter flask. (2) This modification is shown in Fig. 29. Into the narrow part of the funnel an indiarubber bung is fitted, with a perforation in it sufficiently large to receive the candle, which it should grasp tightly.

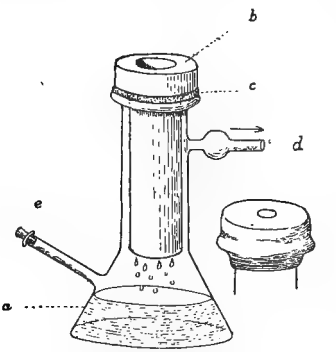

FIG. 30.—Muencke's modification f Chamberland's filter.

(*c*) Muencke's modification of the Chamberland filter is seen in Fig. 30. It consists of a thick-walled flask *a*, the lower part conical, the upper cylindrical, with a strong flange on the lip. There are two lateral tubes, one horizontal to connect with exhaust-pipe, and one sloping, by which the contents may be poured out. Passing into the upper cylindrical part of the flask is a hollow porcelain cylinder *b*, of less diameter than the cylindrical part of flask *a*. It is closed below, open above, and rests by a projecting rim on the flange of the flask, an asbestos washer, *c*, being interposed. The fluid to be filtered is placed in the porcelain cylinder, and the whole top covered, as shown at *f*, with an indiarubber cap with a central perforation; the tube *d* is connected with the exhaust-pump, and the tube *e* plugged with a rubber stopper. For filtering small quantities of fluid the apparatus shown in Fig. 31 may be used. It consists of a small Chamberland bougie fitted by a rubber tube

to a funnel, the stem of which has been passed through a rubber cork; this cork fits into a conical flask with side arm for connection with exhaust.

Before any one of the above apparatus is used it ought to be connected up as far as possible and sterilised in the Koch's steriliser. The ends of any important unconnected parts ought to have pieces of cotton wool tied over them. After use the bougie is to be sterilised in the autoclave. Much of the material kept back on the filter can now be removed by forcing water through in a direction opposite to that of the flow of the fluid during filtration. Alternatively, the candle, after being dried, should be passed carefully through a Bunsen flame to burn off all organic matter. If the latter is allowed to accumulate, the pores become filled up.

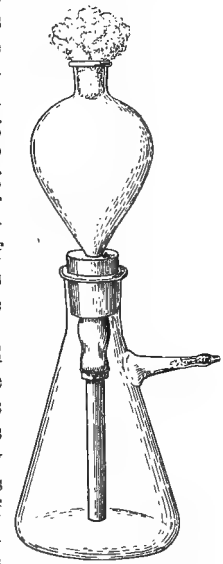

FIG. 31. — Flask for filtering small quantities of fluid.

The success of filtration must be tested by inoculating tubes of media from the filtrate, and observing if growth takes place, as there may be minute perforations in a candle sufficiently large to allow bacteria to pass through. Filtered fluids keep for a long time if the openings of the glass vessels in which they are placed are kept thoroughly closed, and if these vessels be stored in a cool place in the dark. A layer of sterile toluol about half an inch thick ought to be run on to the top of the filtered fluid to protect it from the atmospheric oxygen.

Instead of being filtered off, the bacteria may be killed by various antiseptics, chiefly volatile oils, such as oil of mustard (Roux). These oils are stated to have no injurious effect on the chemical substances in the fluid, and they may be subsequently removed by evaporation. It is not practicable to kill the bacteria by heat when their soluble products are to be studied, as many of the latter are destroyed by a lower temperature than is required to kill the bacteria themselves.

Bacteria can be almost entirely removed from fluid cultures by spinning the latter in a centrifuge of very high speed (*e.g.*, C. J. Martin's turbine centrifuge), and this method is sometimes adopted in practice.

The Observation of Bacterial Fermentation of Sugars, etc.—The capacity of certain species of bacteria to originate fermentations in sugars constitutes an important biological factor. It is well to consider this factor in relation to the chemical constitution of the sugars. The true sugars are aldehydes or ketones, one or more of the carbon atoms of which is united to a hydroxyl group, one being directly linked to a carbon atom in union with carbonyl. The group characteristic of a sugar is thus $-CHOH-CO-$. The sugars are divided into monosaccharides, disaccharides, and polysaccharides. The members of the last two groups may be looked on as derived from the combination of two or more molecules of a monosaccharide with the elimination of water (*e.g.*, $2C_6H_{12}O_6 = C_{12}H_{22}O_{11} + H_2O$), but their chemical constitution may be more complex than that of the first group.

Monosaccharides.—These are classified according to the number of C atoms they contain. The pentoses ordinarily used are arabinose (obtained from gum arabic), xylose (from wood), and rhamnose (which is really a methylpentose). Among the hexoses are glucose (dextrose) with dextro-rotatory properties. Glucose is an aldehyde (aldose), but in fruit there is also a ketone (ketose) called fructose, which from its lævo-rotatory properties is also known as lævulose. Other hexoses are mannose (from the vegetable ivory nut) and galactose (a hydrolytic derivative of lactose).

Disaccharides ($C_{12}H_{22}O_{11}$).—The ordinary members of this group are maltose (derived from starch), lactose, and cane sugar (sucrose, saccharose).

Polysaccharides.—Examples are starch, raffinose, inulin (from dahlia roots), dextrin, arabin, glycogen, cellulose.

If we consider sugars generally from the point of view of the capacity of yeast to originate alcoholic fermentation in them, we may say that the simpler the constitution of the sugar the more easily is it fermented. Thus the monosaccharides are more easily acted on by yeast than the di- or poly-saccharides. Usually an independent process resulting in the splitting of the higher into the lower is preliminary to the alcoholic fermentation. Thus yeast first inverts cane sugar into glucose and fructose, and then acts on these products. From what is known it is probable that similar facts hold with regard to the action of bacteria.

Besides sugars, closely allied bodies which are alcohols with large molecules may be broken down by bacterial action, and these have been used for differentiating the properties of allied

bacteria. Among such substances may be mentioned the trihydric alcohol glycerol (glycerin), the tetrahydric erythritol, the pentahydric adonitol, and the hexahydric dulcitol (dulcite), mannitol (mannite), and sorbitol (sorbite).

Similarly glucosides (which are combinations of glucose with other substances), such as salicin, coniferin, etc., have been used for testing the fermentative properties of bacteria. Other substances allied to sugars (*e.g.*, inosite) have also been used.

The end products of bacterial fermentations may be various. They differ according to the sugar employed and according to the species of bacterium under observation, and frequently a species which will ferment one sugar has no effect on another. The substances finally produced, speaking roughly, may be alcohols, acids, or gaseous bodies (chiefly carbon dioxide, hydrogen, and methane). For the estimation of the first groups complicated chemical procedure may be necessary. The tests usually employed for the detection of ordinary fermentative processes depend on two kinds of changes, namely, (*a*) the evolution of gases and (*b*) the formation of acids. Generally speaking, we may say that these tests are reliable, and the methods to be pursued are simple. Besides such gases as those named, some organisms give rise to sulphuretted hydrogen by breaking up the proteid. The formation of this gas can be detected by the blackening of lead acetate when it is added to the gas-containing medium.

In testing the effect of a bacterium on a given sugar it is essential that this sugar alone be present; the basis of the medium ought therefore to be either peptone solution (*vide* p. 39), Hiss's serum water medium (p. 46), or a dextrose-free bouillon (*vide infra*). The sugar or other substance is added in the proportion of from a half to one per cent., and care is taken not to overheat during sterilisation.

It is preferable that the addition should be made in the form of a sterile solution in water. If the sugar in solid form be placed in the bouillon and this then sterilised, there is danger that chemical changes may take place in the sugar, in consequence of its being heated in the presence of substances (such as alkalies) which may act deleteriously upon it; in any case sterilisation should not be at a temperature above 100° C.

To obtain a "dextrose-free" bouillon it is usual to inoculate ordinary bouillon with some organism, such as b. coli, which is known to ferment dextrose, and allow it to act for forty-eight hours. The bouillon is then filtered and re-sterilised. A sample is tested for another period of forty-eight hours with b. coli, to make certain that all the dextrose has been removed. If no fresh gas-formation is observed, then to the remainder of the bouillon the sugar to be investigated may be added.

It is to be noted, however, that a bouillon rendered "dextrose-free" by b. coli may still contain carbohydrate fermentable, for example, by a streptococcus.

For *the observation of gas-formation* either of the following methods may be employed :—

(1) *Durham's Tubes* (Fig. 32, *b*).—The plug of a tube which contains about one-third more than usual of a liquid medium is removed, and a small test-tube is inverted and slipped down into the medium. The plug is replaced and the tube sterilised thrice for ten minutes at 100° C. The air remaining

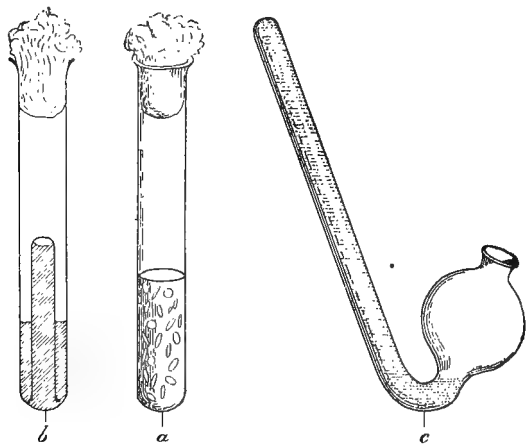

FIG. 32.—Tubes for demonstrating gas-formation by bacteria.

a, tube with "shake" culture.
b, Durham's fermentation tube.
c, ordinary form of fermentation tube.

in the smaller tube is thereby expelled. The tube is then inoculated with the bacterium to be tested. Any gas developed collects in the upper part of the inner tube. As some of the sugars now used for fermentation tests are rather expensive, it is well to arrange the Durham apparatus with very small tubes; with these a satisfactory result can be obtained with only 1 c.c. of medium.

(2) *The Fermentation Tube* (Fig. 32, *c*).—This consists of a tube of the form shown, and the figure also indicates the extent to which it ought to be filled. It is inoculated in the bend with the gas-forming organism, and when growth occurs the gas

collects in the upper part of the closed limb, the medium being displaced into the bulb. If the limb be graduated the amount of gas evolved can be measured, and rough chemical tests can be applied, *e.g.*, the presence of carbonic acid gas can be tested for by absorbing it with a solution of caustic soda and that of hydrogen by ignition (see under b. coli).

The *development of an acid reaction* is demonstrated by the addition of an indicator to the medium, litmus or neutral-red being generally used. The details of the composition of such media have already been given. In Hiss's serum water media the production of acid also leads to coagulation of the medium. Sometimes acid is formed very slowly from sugars, so that it is well to keep the cultures under observation for several days.

Acid and gas-formation may be simultaneously tested for, by placing the fluid medium containing the indicator in Durham's tubes.

In all tests in which sugars are used, a control uninoculated tube ought to be incubated along with the bacterial cultures, as changes in reaction sometimes spontaneously occur in media containing unstable sugars. Tests in which sugars are used are best carried out in Jena glass tubes.

The capacity of an organism to produce acid may be measured by taking a standard amount of a fluid medium and allowing growth to take place for a standard time, and then adding an amount of, say, decinormal soda solution sufficient to bring the litmus back to the tint of the original medium.

The Observation of Indol-formation by Bacteria.— The formation of indol from protein by a bacterium sometimes constitutes an important specific characteristic. To observe indol production the bacterium is grown, preferably at incubation temperature, in a fluid medium containing peptone. The latter may either be sugar-free bouillon or preferably peptone solution (see p. 39). Any medium containing sugars must be avoided, as the presence of these substances may inhibit the production of indol. Two methods are in use for the detection of this body.

(1) *The Nitroso-indol Method.*—Indol is here recognised by the fact that when it is acted on by nitric acid *in the presence of nitrites*, a nitroso-indol compound is produced, which has a rosy red colour. Some bacteria (*e.g.*, the cholera vibrio) produce nitrites as well as indol, but usually in making the test (*e.g.*, in the case of b. coli) the nitrites must be added. This is effected by adding to an ordinary tube of medium 1 c.c. of a ·02 per cent. solution of potassium nitrite, and testing with pure nitric

or sulphuric acid. In any case only a drop of the acid need be added to, say, 10 c.c. of medium. If no result be obtained at once it is well to allow the tube to stand for an hour, as sometimes the reaction is very slowly produced. In many instances incubation at 37° C. for several days may be necessary before the presence of indol is demonstrable. The amount of indol produced by a bacterium seems to vary very much with certain unknown qualities of the peptone. It is well, therefore, to test a series of peptones with an organism (such as the b. coli) known to produce indol, and, noting the sample with which the best reaction is obtained, to reserve it for making media to be used for the detection of this product. This method has for long been felt not to be satisfactory, and the following at present bids fair to replace it :—

(2) *Ehrlich's Rosindol Reaction.*—The adaptation of this to bacteriological purposes was brought forward by Böhme in 1906. For ease of application and delicacy of effect the reaction possesses great advantages. It depends on the fact that paradimethylamidobenzaldehyde unites with indol to form a rosindol body whose colour is readily developed, especially in presence of an oxidising substance such as potassium persulphate ($K_2S_2O_8$). Two solutions are required :—

(1)	Paradimethylamidobenzaldehyde .	4 grms.
	Absolute alcohol (96 per cent.) . .	380 c.c.
	Concentrated hydrochloric acid . .	80 c.c.
(2)	Potassium persulphate .	Saturated watery solution.

To a culture of the organism in 5 c.c. of peptone water add 1 c.c. of (1) and then 1 c.c. of (2), and shake well; if indol be present a rose-red colour will appear in a few minutes. Sometimes the rose colour appears on the addition of solution (1), and the addition of a special oxidising agent is unnecessary. The rosindol compound can be separated from the culture by shaking the latter up with amyl alcohol, and MacConkey recommends that this should be done in cases of a doubtful reaction, as sometimes when a faint pink colour appears in the culture tube the extracting alcohol remains colourless, showing that no real reaction has occurred. Marshall has pointed out that by means of the reaction a quantitative estimate of the amount of indol formation can be obtained. To do this a large culture, say 100 c.c., is distilled, and the colour obtained by applying the test to the distillate in a Nessler's tube is matched against that obtained with different amounts of a standard solution of indol

(prepared by dissolving 1 gr. indol in 5 c.c. absolute alcohol, and making up to 500 c.c. with distilled water).

There is no doubt that the Ehrlich test is from five to ten times more delicate than the ordinary nitroso-indol reaction, and it is of especial value in dealing with organisms of the coli-typhoid group. With strains of b. coli it can often be obtained in from twenty-four to forty-eight hours, but in the case of a negative result a culture of from six to seven days ought to be used. The reaction is also obtainable with the cholera vibrio, but further investigation is here necessary, as Marshall states that under certain circumstances the nitrites formed by this bacterium may have an inhibitory effect on the production of the rose colour.

The Drying of Substances *in vacuo*.—As many substances, for example toxins and antitoxins, with which bacteriology is concerned would be destroyed by drying with heat as is done in ordinary chemical work, it is necessary to remove the water at the ordinary room temperature. This is most quickly effected by drying *in vacuo* in the presence of some substance such as strong sulphuric acid, which readily takes up water vapour. The vacuum produced by a water-pump is here not available, as in such a vacuum there must always be water vapour present. An air-pump is therefore to be employed. Here we have found the Geryk pump most efficient, and it has this further advantage, that its internal parts are lubricated with an oil of very low vapour density, so that almost a perfect vacuum is obtainable. The apparatus is shown in Fig. 33. The vacuum chamber consists of a bell-jar set on a brass plate. A perforation in the centre of the latter leads into the pipe *b*, which can be connected by strong-walled rubber-tubing with the air-pump, and which can be cut off from the latter by a stop-cock *a*. In using the apparatus the substance to be dried is poured out in flat dishes (one-half of a Petri capsule does very well), and these are stacked alternately with similar dishes of strong sulphuric acid on a stand which rests on the brass plate. The edge of the bell-jar is well luted with unguentum resinæ and placed in position and the chamber exhausted. In a few hours, if, as is always advisable, each dish have contained only a thin layer of fluid, the drying will be complete. The vacuum is then broken by admitting air very slowly through a bye-pass *c*, and the bell-jar is removed. In such an apparatus it is always advisable, as is shown in the figure, to have interposed between the pump and the vacuum chamber a Wolff's bottle containing sulphuric acid. This protects the oil of the pump from contamination with

water vapour. Whenever the vacuum is produced the rubber-tube should be at once disconnected from *b*, the cock *a* being shut. It is advisable when the apparatus is exhausted to cover the vacuum chamber and the Wolff's bottle with wire guards covered with strong cloth, in case, under the external pressure, the glass vessels give way. The connecting and disconnecting of rubber-tubing of sufficient thickness to withstand collapse when exhausted is difficult. Ordinary stout rubber-tubing can be used if through it there is passed a length of narrow flexible metal-tubing, the ends of which project beyond the rubber-tubing

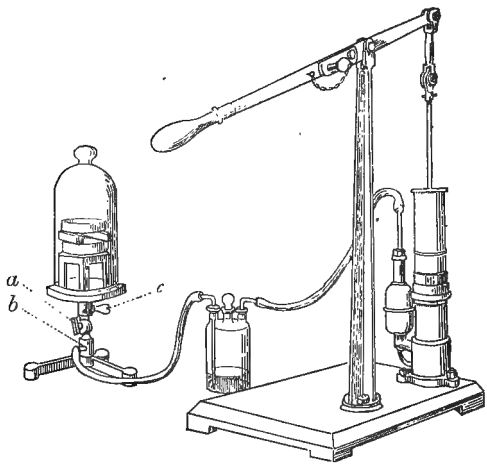

FIG. 33.—Geryk air-pump for drying *in vacuo*.

so as to enter the parts of the apparatus to which the latter is fitted.

The Storing and Incubation of Cultures.—Gelatin cultures must be grown at a temperature below their melting-point, *i.e.*, for 10 per cent. gelatin, below 22° C. They are usually kept in ordinary rooms or in a cool incubator at about 20° C. Agar and serum media are employed to grow bacteria at a higher temperature, corresponding to that at which the organisms grow best, usually 37° C. in the case of pathogenic organisms. For the purpose of maintaining a uniform temperature incubators are used. These vary much in the details of their structure, but all consist of a chamber with double walls between which some fluid (water or glycerin and water) is placed.

This, when raised to a certain temperature, ensures a fairly constant distribution of the heat round the chamber. The latter is also furnished with double doors, the inner being usually of glass. Heat is supplied from a burner fixed below. These burners vary much in design. Sometimes a mechanism devised in Koch's laboratory is affixed, which automatically turns off the gas if the light be accidentally extinguished. Between the tap supplying the gas, and the burner, is interposed a gas regulator. Such regulators vary in design, but, for ordinary chambers which require to be kept at a constant temperature, Reichert's is as good and simple as any, and is not expensive. It is shown in Fig. 34.

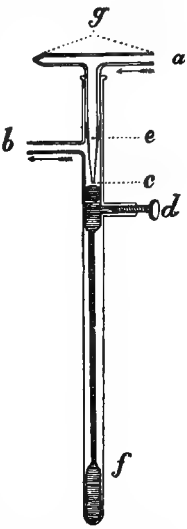

FIG. 34.—Reichert's gas regulator.

The gas enters at *a* and from *b* passes to the burner. When the mercury in *f* expands to cut off the gas at *c* sufficient passes by the bye-pass *e* to keep the flame alight. There is an improved form with a large bulb filled with xylol attached at *f*. Changes in the bulk of the xylol are communicated to the mercury. This instrument is very delicate and will be found to work well.

The varieties of incubators are, as we have said, numerous. We have found those of Hearson of London extremely good, and they are fitted with a good regulator. It is preferable in using an incubator to connect the regulator with the gas supply and with the Bunsen by flexible metal-tubing. It is necessary to see that there is not too much evaporation from the surface of cultures placed within incubators, otherwise they may quickly dry up. It is thus advisable to raise the amount of water vapour in the interior by having in the bottom of the incubator a flat dish full of water from which evaporation may take place. With tubes which will require to be long in the incubator, the plugs should be pushed a little way into the tube and a few drops of melted paraffin dropped on the top of the wool, or the plugs should be covered either by indiarubber caps or by pieces of sheet rubber tied over them. These caps should be previously sterilised in 1–1000 corrosive sublimate and then dried. Before they are placed on the tube the cotton-wool plug ought to be well singed in a flame. "Cool" incubators are often used for incubating gelatin at 21° to

22° C. An incubator of this kind fitted with a low-temperature Hearson's regulator is in the market.

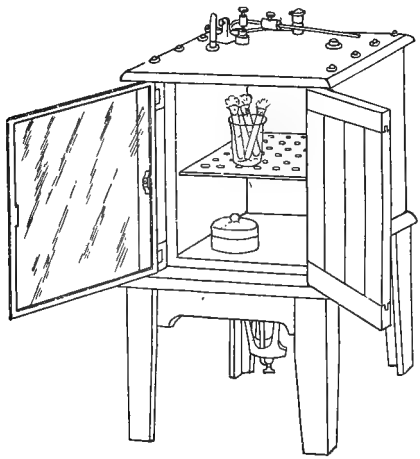

FIG. 35.—Hearson's incubator for use at 37° C.

Method of Mounting Bacterial Cultures as Permanent Museum Specimens (Richard Muir). — (*a*) *Stab or Stroke Cultures in Nutrient Gelatin or Agar Media.*—When the culture shows typical characters, further growth is arrested by placing the tube in a formol vapour chamber, or by saturating the cotton-wool plug with strong formalin. Then leave for a day or two. Make up the following :—

(1) Thymol water (saturated in cold) . . .	100 c.c.
Glycerin	20 c.c.
Acetate of potash . . .	5 grms.
Coignet's (gold label) gelatin . . .	10 grms.

Render the mixture acid to litmus with acetic acid ; clear with white of egg and filter.

Warm to about 40° C., and, removing cotton-wool plug from culture, take a little of the preserving fluid in a pipette and allow to run gently over surface of medium in tube. Place in such a position that a thin layer of the preserving medium remains completely covering the growth and the surface of culture medium. The gelatin is now allowed to solidify. Add three or four drops of strong formalin to the tube, and fill up to

within a quarter of an inch of the top of the tube with the following fluid :—

(2) Thymol water (saturated in cold) . . .	100 c.c.
Glycerin	20 c.c.
Acetate of potash	5 grms.

Cover top of tube with a small piece of paper so as to keep out dust, allow to stand for a day or two so that small air-bells may rise to the surface.

To seal tube, pour melted paraffin gently on to the surface of fluid up to near the top of tube; allow to solidify. Cover paraffin with layer of alcoholic orange shellac cement; allow this to set, and repeat until the cement becomes level with top of test-tube. When the cement is set, a few drops of black lacquer are put on, and a circular cover-glass of about the same diameter as the mouth of tube is placed so as completely to seal it.

(*b*) The following method is useful for preserving *plate cultures* : Instead of making the cultures in Petri's capsules, use ordinary watch-glasses. The watch-glass is sterilised in a Petri's capsule, and the inoculated medium is poured out into the watch-glass, allowed to solidify in the usual way, and left in the Petri's capsule until the colonies of growth have developed. The watch-glass is now removed from capsule, and a layer of the preserving gelatin medium (1) (p. 86), to which have been added a few drops of strong formalin, is allowed to spread over the surface of the culture medium. When the layer is solidified the watch-glass is filled up with the same, and a clean square or oblong piece of glass (which of course should be of slightly larger diameter than the watch-glass) is now carefully placed over watch-glass, care being taken that no air-bells are formed. The edge of watch-glass should be closely applied to the glass cover, and left in position until the gelatin has solidified. The superfluous gelatin is now removed, and the glasses sealed first with the orange shellac cement, then with black lacquer. It is now finished off by using a circular mask of suitable size.

The various kinds of solid media used in the cultivation of bacteria, such as blood serum, potato, bread paste, etc., can be treated in the same manner with excellent results.

General Laboratory Rules.—On the working bench of every bacteriologist there should be a large dish of 1–1000 solution of mercuric chloride in water. Into this all tubes, vessels, plates, hanging-drop cultures, etc., which have contained bacteria and with which he has finished, ought to be at once plunged (in the

case of tubes, the tube and plug should be put in separately). On no account whatever are such infected articles to be left lying about the laboratory. The basin is to be repeatedly cleaned out. All the glass is carefully washed in repeated changes of tap water to remove the last trace of perchloride of mercury, a very minute quantity of which is sufficient to inhibit growth. Old cultures which have been stored for a time, and from which fresh sub-cultures have been made, ought to be steamed in the Koch's steriliser for two or three hours, or in the autoclave for a shorter period, and the tubes thoroughly washed out. Besides a basin of mercuric chloride solution for infected apparatus, etc., there ought to be a second reserved for the worker's hands in case of any accidental contamination. When, as in public-health work, a large number of tubes are being daily put out of use, they may be placed in an enamelled slop-pail, and this when full is placed in the steam steriliser.

A white glazed tile on which a bell-jar can be set is very convenient to have on a bench. Infective material in watch-glasses can be placed thus under cover while investigation is going on, and if anything is spilled the whole can be easily disinfected. In making examinations of organs containing virulent bacteria, the hands should be previously dipped in 1–1000 mercuric chloride and allowed to remain wet with this solution. No food ought to be partaken of in the laboratory, and pipes, etc., are not to be laid with their mouth-pieces on the bench. No label is to be licked with the tongue. Before leaving the laboratory the bacteriologist ought to wash the hands and forearms with 1–1000 mercuric chloride and then with yellow soap. In the case of any fluid containing bacteria being accidentally spilt on the bench or floor, 1–1000 mercuric chloride is to be at once poured on the spot. The air of the laboratory ought to be kept as quiet as possible.

CHAPTER III.

MICROSCOPIC METHODS.

The Microscope.—For ordinary bacteriological work a good microscope is essential. It ought to have a heavy stand, with coarse and fine adjustments, a double mirror (flat on one side, concave on the other), a good condenser, with an iris diaphragm, and a triple nose-piece. It is advisable to have three objectives, ordinary low and high powers, and a $\frac{1}{12}$-inch oil immersion, which is essential. It is well to have two eye-pieces. The student must be thoroughly familiar with the focusing of the light on the lens by means of the condenser, and also with the use of the immersion lens. It may here be remarked that when it is desired to bring out in sharp relief the margins of unstained objects, *e.g.*, living bacteria in a fluid, a narrow aperture of the diaphragm should be used, whereas, in the case of stained bacteria, when a pure coloured picture is desired, the diaphragm ought to be widely opened. The flat side of the mirror ought to be used along with the condenser. When the observer has finished for the time being with the immersion lens he ought to wipe off the oil with a piece of silk or very fine washed linen. If the oil has dried on the lens it may be moistened with xylol —never with alcohol, which will dissolve the material by which the lens is fixed in its metal carrier.

Microscopic Examination of Bacteria.—1. **Hanging-drop Preparations.**—Micro-organisms may be examined: (1) alive or dead in fluids; (2) in film preparations; (3) in sections of tissues. In the two last cases advantage is always taken of the affinity of bacteria for certain stains. When they are to be examined in fluids a drop of the liquid may be placed on a slide and covered with a cover-glass.[1] It is more usual, however, to employ hanging-drop preparations. The technique of making

[1] In bacteriological work it is essential that cover-glasses of No. 1 thickness (*i.e.*, ·14 mm. thick) should be used, as those of greater thickness are not suitable for a $\frac{1}{12}$-inch lens.

these has already been described (p. 70). In examining them microscopically, it is necessary to use a very small diaphragm. It is best to focus the edge of the drop with a low-power objective, and, arranging the slide so that part of the edge crosses the centre of the field, to clamp the preparation in this position. A high-power lens is then turned into position, and lowered by the coarse adjustment to a short distance above its focal distance; it is now carefully screwed down by the fine adjustment, the eye being kept at the tube meanwhile. The shadow of the edge will be first recognised, and then the bacteria must be carefully looked for. Often a dry lens is sufficient, but for some purposes the oil immersion is required. If the bacteria are small and motile, a beginner may have great difficulty in seeing them, and it is well to practise at first on some large non-motile form, such as anthrax. In fluid preparations the natural appearance of bacteria may be studied, and their rate of growth determined. The great use of such preparations, however, is to find whether or not the bacteria are motile, and for determining this point it is advisable to use either broth or agar cultures not more than twenty-four hours old. In the latter case a small fragment of growth is broken down in broth or in sterile water. Sometimes it is an advantage to colour the solution in which the hanging-drop is made up with a minute quantity of an aniline dye, say a small crystal of gentian violet to 100 c.c. of bouillon. Such a degree of dilution will not have any effect on the vitality of the bacteria. Ordinarily, living bacteria will not take up a stain, but even though they do not, the contrast between the unstained bacteria and the tinted fluid will enable the observer more easily to recognise them. In determining whether or not a bacterium is motile, great difficulty is often experienced in distinguishing between true motion and Brownian movement, especially if the organism be small. The essential criterion to be fulfilled is that the bacteria shall be moving in all directions, the observation of individuals lying close together starting to move in opposite directions being important. The observation of hanging-drop preparations must be correlated with the results of staining for the presence of flagella which, so far as is known, are present in all ordinary motile forms.

Dark-Ground Illumination.—Within recent years the method of observing living micro-organisms by oblique illumination has been much practised, and a number of substage condensers are in the market, by means of which this is effected. The general principle involved in these instruments is to stop out the rays passing directly towards the tube of the microscope, and to

arrange for light being thrown obliquely on objects, *e.g.*, bacteria, mounted in a drop of fluid between a slide and cover-glass. The bacteria disperse these rays in all directions, and some passing up through the lens can be focused by it. It is also necessary to place a suitable stop within the objective of the microscope to cut off the peripheral rays. The organisms appear as brightly illumined objects on a dark background. The method has been employed for bacteria in general, and especially for the demonstration of spirochætes in secretions. Generally speaking, the internal structure of the organisms under observation is well brought out, and their movements can be readily studied.

2. **Film Preparations.**—(*a*) *Dry Method.*—This is the most extensively applicable method for microscopically examining bacteria. Fluids containing bacteria, such as blood, pus, scrapings of organs, can be thus investigated, as also cultures in fluid and solid media. The first requisite is a perfectly clean cover-glass or slide. Many methods are recommended for obtaining such. The test of this being accomplished is that, when the drop of fluid containing the bacteria is placed upon the glass, it can be uniformly spread with the platinum needle all over the surface without showing any tendency to retract into droplets. The best method is that recommended by Van Ermengem. The cover-glasses or slides are placed for some time in a mixture of concentrated sulphuric acid 6 parts, potassium bichromate 6 parts, water 100 parts, then washed thoroughly in water and dried. If a fluid is to be examined a loopful may be placed on the cover-glass and spread out over the surface with the needle. When a culture on a solid medium is to be examined, a loopful of water is placed on the cover-glass, and a minute particle of growth rubbed up in it and spread over the glass. The great mistake made by beginners is to take too much of the growth. The point of the straight needle should just touch the surface of the culture, and when this is rubbed up in the droplet of water and the film dried, there should be an opaque cloud just visible on the cover-glass. When a film has been spread, it must next be dried by being waved backwards and forwards at arm's-length above a Bunsen flame. The film must then be fixed on the glass by being passed three or four times slowly through the flame. In doing this a good plan is to hold the glass between the right forefinger and thumb; if the fingers just escape being burned no harm will accrue to the bacteria in the film.

In ordinary routine examinations it is more convenient to

make films on clean glass slides. After these are fixed and stained they may be examined without a cover-glass, a drop of cedar-oil being placed on the film. If such a preparation is to be preserved, the oil should be removed by xylol, which is then dried off, and the slide may then be kept in a box free from dust. In making films of a thick fluid such as *pus* it is best to spread it out with the needle. The result will be a film of irregular thickness, but sufficiently thin at many parts for proper examination. It is often advisable to dilute the material by emulsifying with a loop of water. Scrapings of organs may be smeared directly on a cover-glass or slide.

FIG. 36.—Cornet's forceps for holding cover-glasses.

In the case of *blood*, a small drop is placed near one end of a clean slide, the edge of a second slide is lowered through the drop on to the surface of the glass on which the blood has been placed. This second slide is held at an angle to the first, and the droplet of blood by capillarity spreads itself in the angle between the two slides. The edge of the second slide is then stroked along the surface of the first slide, and the blood is spread out in a film whose thickness can be regulated by the angle formed by the second slide. Large-sized films can thus be obtained. A film prepared in this way may be too thick at one edge, but at the other is beautifully thin. Another method is to allow a drop of blood to spread itself between two clean cover-glasses, which are then to be slipped apart, and being held between the forefinger and thumb are to be dried by a rapid to-and-fro movement in the air. If it is desired to preserve the red blood corpuscles in a film it may be fixed by one of the following methods: by being placed (*a*) in a hot-air chamber at 120° C. for half an hour; (*b*) in a mixture of equal parts of alcohol and ether for half an hour, then washed and dried; (*c*) in formol-alcohol (Gulland) (formalin 1 part, absolute alcohol 9 parts) for five minutes, then washed and dried; or (*d*) in a saturated solution of corrosive sublimate for two or three minutes, then washed well in running water and dried. (Fig. 61 shows a film prepared by the last method.) In using the Romanowsky stains no previous fixation is necessary (*vide infra*).

In the case of *urine*, the specimen must be allowed to stand, and films made from any deposit which occurs; or, what is still better, the urine is centrifugalised, and films made from the deposit which forms. After dried films are thus made from

urine it is an advantage to place a drop of distilled water on the film and heat gently to dissolve the deposit of salts; then gently wash in water and dry. In this way a much clearer picture is obtained when the preparation is stained.

Films dried and fixed by the above methods are now ready to be stained by the methods to be described below.

(*b*) *Wet Method.*—If it is desired to examine the fine histological structure of the cells of a discharge as well as to investigate the bacteria present, it is advisable to substitute "wet" films for the "dried" films, the preparation of which has been described. The nuclear structure, mitotic figures, etc., are by this method well preserved, whereas these are considerably distorted in dried films. The initial stages in the preparation of wet films are the same as above, but instead of being dried in air they are placed, while still wet, film downwards in the fixative. The following are some of the best fixing methods :—

(*a*) A saturated solution of perchloride of mercury in ·75 per cent. sodium chloride; fix for five minutes. Then place the films for half an hour, with occasional gentle shaking, in ·75 per cent. sodium chloride solution to wash out the corrosive sublimate; they are thereafter washed in successive strengths of methylated spirit. After this treatment the films are stained and treated as if they were sections.

(*b*) Formol-alcohol—formalin 1 part, absolute alcohol 9. Fix films for three minutes; then wash well in methylated spirit. This is an excellent and very rapid method.

(*c*) Another excellent method of fixing has been devised by Gulland. The fixing solution has the composition—absolute alcohol 25 c.c., pure ether 25 c.c., alcoholic solution of corrosive sublimate (2 grms. in 10 c.c. of alcohol) about 5 drops. The films are placed in this solution for five minutes or longer. They are then washed well in water, and are ready for staining. A contrast stain can be applied at the same time as the fixing solution, by saturating the 25 c.c. of alcohol with eosin before mixing. Thereafter the bacteria, etc., may be stained with methylene-blue or other stain, as described below. This method has the advantage over (*a*) that, as a small amount of corrosive sublimate is used, less washing is necessary to remove it from the preparation, and deposits are less liable to occur.

3. **Examination of Bacteria in Tissues.**—For the examination of bacteria in the tissues, the latter must be fixed and hardened, in preparation for being cut with a microtome. Fixation consists in so treating a tissue that it shall permanently maintain, as far as possible, the condition it was in when removed from the body. Hardening consists in giving such a fixed tissue sufficient consistence to enable a thin section of it to be cut. A tissue, after being hardened, may be cut in a freezing microtome (*e.g.*, Cathcart's or one of the newer instru-

ments in which the freezing is accomplished by compressed carbonic acid gas), but far finer results can be obtained by embedding the tissue in solid paraffin and cutting with some of the more delicate microtomes of which, for pathological purposes, the small Cambridge rocker is by far the best. For bacteriological purposes embedding in celloidin is not advisable, as the celloidin takes on the aniline dyes which are used for staining bacteria, and is apt thus to spoil the preparation, and besides, thinner sections can be obtained by the paraffin method.

The Fixation and Hardening of Tissues.—The following are amongst the best methods for bacteriological purposes :—

(*a*) *Absolute alcohol* may be used for the double purpose of fixing and hardening. If the piece of tissue is not more than $\frac{1}{8}$ inch in thickness, it is sufficient to keep it in this reagent for a few hours. If the pieces are thicker a longer exposure is necessary, and in such cases it is better to change the alcohol at the end of the first twenty-four hours. The tissue must be tough without being hard, and the necessary consistence, as estimated by feeling with the fingers, can only be judged of after some experience. If the tissues are not to be cut at once, they may be preserved in 50 per cent. spirit.

(*b*) *Formalin solution.*—This may be used as a 10 per cent. solution of commercial formol-aldehyde in water. Small pieces of tissue are fixed in this in twenty-four hours; they are then placed in 50 per cent. spirit for a similar period, and then in pure spirit.

(*c*) *Formol-alcohol*—formalin 1, absolute alcohol 9. Fix for not more than twenty-four hours; then place in absolute alcohol if the tissue is to be embedded at once, in 50 per cent. spirit if it is to be kept for some time. For small pieces of tissue fixation for twelve hours or even less is sufficient. The method is a rapid and very satisfactory one.

(*d*) *Corrosive sublimate* is an excellent fixing agent. It is best used as a saturated solution in ·75 per cent. sodium chloride solution. Dissolve the sublimate in the salt solution by heat; the separation of crystals on cooling shows that the solution is saturated. For small pieces of tissue $\frac{1}{8}$ inch in thickness, twelve hours' immersion is sufficient. If the pieces are larger, twenty-four hours is necessary. They should then be tied up in a piece of gauze, and placed in a stream of running water for from twelve to twenty-four hours, according to the size of the pieces, to wash out the excess of sublimate. They are then placed for twenty-four hours in each of the following strengths of methylated spirit (free from naphtha [1]): 30 per cent., 60 per cent., and 90 per cent. Finally they are placed in absolute alcohol for twenty-four hours, and are then ready to be prepared for cutting.

If the tissue is very small, as in the case of minute pieces removed for diagnosis, the stages may be all compressed into twenty-four hours.

[1] In Britain ordinary commercial methylated spirit has mineral naphtha added to it to discourage its being used as a beverage. The naphtha being insoluble in water a milky fluid results from the dilution of the spirit. By law, chemists can only sell 8 ounces of pure spirit at a time. Most pathological laboratories are, however, permitted by the Excise to buy "industrial spirit," which contains only one-nineteenth of wood naphtha.

In fact, after fixation in corrosive the tissue may be transferred directly to absolute alcohol, the perchloride of mercury being removed after the sections are cut, as will be afterwards described.

The Cutting of Sections.—1. *By Means of the Freezing Microtome.*—Pieces of tissue hardened by any of the above methods must have all the alcohol removed from them by washing in running water for twenty-four hours. They are then placed for from twelve to twenty-four hours (according to their size) in a thick syrupy solution containing two parts of gum arabic and one part of sugar. They are then cut on a freezing microtome and placed for a few hours in a bowl of water so that the gum and syrup may dissolve out. They are then stained, or they may be stored in methylated spirit.

2. *Embedding and Cutting in Solid Paraffin.*—This method gives by far the finest results, and should always be adopted when practicable. The principle is the impregnation of the tissue with paraffin in the melted state. This paraffin when it solidifies gives support to all the tissue elements. The method involves that, after hardening, the tissue shall be thoroughly dehydrated, and then thoroughly permeated by some solvent of paraffin which will expel the dehydrating fluid and prepare for the entrance of the paraffin. The solvents most in use are chloroform, cedar oil, xylol, and turpentine; of these, chloroform is the most suitable. The more gradually the tissues are changed from reagent to reagent in the processes to be gone through, the more successful is the result. A necessity of the process is an oven with hot-water jacket, in which the paraffin can be kept at a constant temperature just above its melting-point, a gas regulator being of course necessary. The tissues occurring in pathological work have a tendency to become brittle if overheated, and therefore the best results are obtained by using paraffin melting at a somewhat low temperature. We have used for some years a mixture of one part of paraffin, melting at 48°, and two parts of paraffin melting at 54° C. This mixture has a melting-point between 52° and 53° C., and it serves all ordinary purposes well. An excellent quality of paraffin is that known as the "Cambridge paraffin," but many scientific-instrument makers supply paraffins which, for ordinary purposes, are quite as good, and much cheaper. The successive steps in the process of paraffin embedding are as follows:[1]—

[1] While the method given is sufficient for ordinary purposes, a more elaborate technique is necessary if it is desired that no changes shall take place in the tissue. Thus after fixation the tissue must be taken up to absolute alcohol

1. Pieces of tissue, however hardened, are placed in fresh absolute alcohol for twenty-four hours in order to their complete dehydration.

2. Transfer now to a mixture of equal parts of absolute alcohol and chloroform for twenty-four hours.

3. Transfer to pure chloroform for twenty-four hours or longer. At the end of this time the tissues should sink or float heavily.

4. Transfer now to a mixture of equal parts of chloroform and paraffin and place on the top of the oven for from twelve to twenty-four hours. If the temperature there is not sufficient to keep the mixture melted then the tissues must be put inside the oven.

5. Place in pure melted paraffin in the oven for twenty-four hours. For holding the paraffin containing the tissues, small tin dishes such as are used by pastry-cooks will be found very suitable. There must be a considerable excess of paraffin over the bulk of tissue present, otherwise sufficient chloroform will be present to vitiate the final result and not give the perfectly hard block obtained with pure paraffin. With experience, the persistence of the slightest trace of chloroform can be recognised by smell.

In the case of very small pieces of tissue the time given for each stage may be much shortened, and where haste is desirable Nos. 2 and 4 may be omitted. Otherwise it is better to carry out the process as described.

6. Cast the tissues in blocks of paraffin as follows: Pairs of L-shaped pieces of metal made for the purpose by instrument makers must be at hand. By laying two of these together on a glass plate, a rectangular trough is formed. This is filled with melted paraffin taken from a stock in a separate dish. In it is immersed the piece of tissue, which is lifted out of its pure paraffin bath with heated forceps. The direction in which it is to be cut must be noted before the paraffin becomes opaque. When the paraffin has begun to set, the glass plate and trough have cold water run over them. When the block is cold, the metal L's are broken off, and, its edges having been pared, it is stored in a pill-box.

The Cutting of Paraffin Sections.—Sections must be cut as thin as possible, the Cambridge rocking microtome being, on the whole, most suitable. They should not exceed 8 μ in thickness, and ought, if possible, to be about 4 μ. For their manipulation

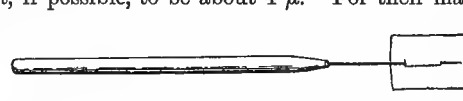

FIG. 37.—Needle with square of paper on end for manipulating paraffin sections.

it is best to have two needles on handles, two camel's-hair brushes on handles, and a needle with a rectangle of stiff writing-paper fixed on it as in the diagram (Fig. 37). When cut, sections are floated on the surface of a beaker of water kept at a temperature

---

through successive dilutions of spirit, not differing from each other by more than 10 per cent. Again, when alcohol has been replaced by chloroform the latter must be saturated with chips of paraffin, first at room temperature, then at 37° C., and must be kept at 55° C. as short a time as possible.

about 10° C. below the melting-point of the paraffin. On the surface of the warm water they become perfectly flat.

Fixation on ordinary Slides.—(*a*) *Gulland's Method.*—A supply of slides well cleaned being at hand, one of them is thrust obliquely into the water below the section, a corner of the section is fixed on it with a needle and the slide withdrawn. The surplus of water being wiped off with a cloth, the slide is placed on a support, with the section downwards, and allowed to remain on the top of the paraffin oven or in a bacteriological incubator for from twelve to twenty-four hours. It will then be sufficiently fixed on the slide to withstand all the manipulations necessary during staining and mounting.

(*b*) *Fixation by Mann's Method.*—This has the advantage of being more rapid than the previous one. A solution of albumin is prepared by mixing the white of a fresh egg with ten parts of distilled water and filtering. Slides are made perfectly clean with alcohol. One is dipped into the solution and its edge is then drawn over one surface of another slide so as to leave on it a thin film of albumin. This is repeated with the others. As each is thus coated it is leant, with the film downwards, on a ledge till dry, and then the slides are stored in a wide stoppered jar till needed. The floating out is performed as before. The albuminised side of the slide is easily recognised by the fact that if it is breathed on, the breath does not condense on it. The great advantage of this method is that the section is fixed after twenty to thirty minutes' drying at 37° C. If the tissue has been hardened in any of the bichromate solutions and embedded in paraffin, this or some corresponding method of fixing the sections on the slide must be used.

Preparation of Paraffin Sections for Staining.—Before staining, the paraffin must be removed from the section. This is best done by dropping on xylol out of a drop bottle. When the paraffin is dissolved out, the superfluous xylol is wiped off with a cloth and a little absolute alcohol dropped on. When the xylol is removed, the superfluous alcohol is wiped off and a little 50 per cent. methylated spirit dropped on. During these procedures sections must on no account be allowed to dry. The sections are now ready to be stained. Deposits of crystals of corrosive sublimate often occur in sections which have been fixed by this reagent. These can be removed by placing the sections, before staining, for a few minutes in equal parts of Gram's iodine solution (p. 103) and water, and then washing out the iodine with methylated spirit.

To save repetition, we shall in treating of stains suppose that, with paraffin sections, the above preliminary steps have already been taken, and further, that sections cut by a freezing microtome are also in spirit and water.

Dehydration and Clearing.—It is convenient, first of all, to indicate the final steps to be taken after a specimen is stained. *Dry films* after being stained are washed in water, dried and

either mounted in xylol balsam or, in the case of films on slides, kept in the dry condition; *wet films* and *sections* must be dehydrated, cleared, and then mounted in xylol balsam.

Dehydration is most commonly effected with absolute alcohol. Alcohol, however, sometimes decolorises the stained organisms more than is desirable, and therefore Weigert devised the following method of dehydrating and clearing by aniline oil, which, though it may decolorise somewhat, does not do so to the same extent as alcohol. As much as possible of the water being removed, the section placed on a slide is partially dried by pressing with fine blotting-paper. Some aniline oil is placed on the section and the slide moved to and fro. The section is dehydrated and becomes clear. The process may be accelerated by heating gently. The preparation is then treated with a mixture of two parts of aniline oil and one part of xylol, and then with xylol alone, after which it is mounted in xylol balsam. Paraffin sections can usually be dehydrated and cleared by the mixture of aniline oil and xylol alone. Balsam as ordinarily supplied has often an acid reaction, and preparations stained with aniline dyes are apt to fade when mounted in it. It is accordingly an advantage to use acid-free balsam.

Sections stained for bacteria should always be *cleared*, at least finally, in xylol, as it dissolves out aniline dyes less readily than such clearing reagents as clove oil, etc. Xylol, however, requires the previous dehydration to have been more complete than clove oil, which will clear a section readily when the dehydration has been only partially effected by, say, methylated spirit. If a little decolorisation of a section is still required before mounting, clove oil may be used to commence the clearing, the process being finished with xylol. With a little experience the process of decolorisation can be judged of by observing the appearances under a low objective.

The Staining of Bacteria.

Staining Principles.—To speak generally, the protoplasm of bacteria reacts to stains in a manner similar to the nuclear chromatin, though sometimes more and sometimes less actively. The bacterial stains *par excellence* are the basic aniline dyes. These dyes are more or less complicated compounds derived from the coal-tar product aniline ($C_6H_5 . NH_2$). Many of them have the constitution of salts. Such compounds are divided into two groups according as the staining action depends on the basic or the acid portion of the molecule. Thus the acetate of

rosaniline derives its staining action from the rosaniline. It is therefore called a basic aniline dye. On the other hand, ammonium picrate owes its action to the picric acid part of the molecule. It is therefore termed an acid aniline dye. These two groups have affinities for different parts of the animal cell. The basic stains have a special affinity for the nuclear chromatin, the acid for the cytoplasm and various formed elements. Thus it is that the former—the basic aniline dyes—are especially the bacterial stains.

The number of basic aniline stains is very large. The following are the most commonly used :—

Violet Stains.—Methyl-violet, R–5R (synonyms : Hoffmann's violet, dahlia).
Gentian-violet (synonyms : benzyl-violet, Pyoktanin).
Crystal violet.

Blue Stains.—Methylene-blue [1] (synonym : phenylene-blue).
Victoria-blue.
Thionin-blue.

Red Stains.—Basic fuchsin (synonyms : basic rubin, magenta).
Safranin (synonyms : fuchsia, Giroflé).

Brown Stain.—Bismarck-brown (synonyms : vesuvin, phenylene-brown).

Of the stains specified, the violets and reds are the most intense in action, especially the former. It is thus easy in using them to overstain a specimen. Of the blues, methylene-blue probably gives the best differentiation of structure, and it is difficult to overstain with it. Thionin-blue also gives good differentiation and does not readily overstain. Its tone is deeper than that of methylene-blue, and it approaches the violets in tint. Bismarck-brown is a weak stain, but is useful for some purposes. Formerly it was much used in photomicrographic work, as it was less actinic than the other stains. It is not, however, needed now, on account of the improved sensitiveness of plates.

It is most convenient to keep saturated alcoholic solutions of the stains made up, and for use to dilute a little with ten times its bulk of distilled water and filter. A solution of good body is thus obtained. Most bacteria (except those of tubercle, leprosy, and a few others) will stain in a short time in such a fluid. Watery solutions may also be made up, *e.g.*, a saturated watery solution of methylene-blue or a 1 per cent. solution of gentian-violet. Stains must always be filtered before use ; otherwise there may be deposited on the preparation granules which it is impossible to wash off. The violet stains

[1] This is to be distinguished from methyl-blue, which is a different compound.

in solution in water have a great tendency to decompose. Only small quantities should therefore be prepared at a time.

The Staining of Films.—Films are made from *cultures* as described above, and a few drops of the stain are placed on the surface. When the preparation has been exposed for the requisite time, usually a few minutes, it is well washed in tap water in a bowl, or with distilled water with such a simple siphon arrangement as that figured (Fig. 38). The figure explains itself. When the film has been washed the surplus of water is drawn off with a piece of filter-paper, the preparation is carefully dried high over a flame, a drop of xylol balsam is applied, and the cover-glass mounted on a slide. It is sometimes advantageous to examine films in a drop of water in place of balsam. The films can be subsequently dried and mounted permanently. In the case of films on slides, a drop of cedar-wood oil is placed on the film directly, and the preparation is then examined.

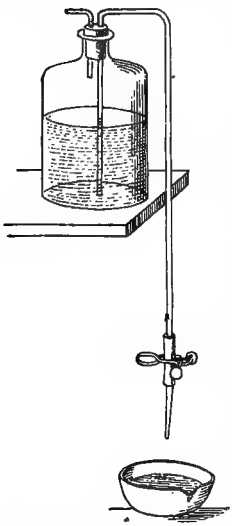

FIG. 38.—Siphon wash-bottle for distilled water used in washing preparations.

Films of *fluids from the body* (blood, pus, etc.) can be generally stained in the same way, and this is often quite sufficient for diagnostic purposes. The blue dyes are here preferable, as they do not readily overstain. In the case of such fluids, if the histological elements also claim attention it is best first to stain the cellular protoplasm with 1–2 per cent. watery solution of eosin (which is an acid dye), and then to use a blue which will stain the bacteria and the nuclei of the cells. The Romanowsky stains (*vide* p. 111) are here most useful, as by these the preparations are fixed as well as stained. Fixation by heat, which is apt to injure delicate cellular structures, is thus avoided. In the case of films made from urine, where there is little or no albuminous matter present, the bacteria may be imperfectly fixed on the slide, and are thus apt to be washed off. In such a case it is well to modify the staining method. A drop of stain is placed on a slide, and the cover-glass, film-side down lowered upon it. After the lapse of the time necessary for

staining, a drop of water is placed at one side of the cover-glass and a little piece of filter paper at the other side. The result is that the stain is sucked out by the filter-paper. By adding fresh drops of water and using fresh pieces of filter-paper, the specimen is washed without any violent application of water, and the bacteria are not displaced.

For the general staining of films a saturated watery solution of methylene-blue will be found to be the best stain to commence with; the Gram method (*vide infra*) is also used, and subsequently any special stains which may appear advisable.

The Use of Mordants and Decolorising Agents.—In films of blood and pus, and still more so in sections of tissues, if the above methods are used, the tissue elements may be stained to such an extent as to quite obscure the bacteria. Hence many methods have been devised in which the general principle may be said to be (*a*) the use of substances which, while increasing the staining power, tend to fix the stain in the bacteria, and (*b*) the subsequent treatment by substances which decolorise the overstained tissues to a greater or less extent, while they leave the bacteria coloured. The staining capacity of a solution may be increased—

(*a*) By the addition of substances such as carbolic acid, aniline oil, or metallic salts.

(*b*) By the addition of alkalies, such as caustic potash or ammonium carbonate, in weak solution.

(*c*) By the employment of heat.

(*d*) By long duration of the staining process.

As decolorising agents we use chiefly mineral acids (hydrochloric, nitric, sulphuric), vegetable acids (especially acetic acid), alcohol (either methylated spirit or absolute alcohol), or a combination of spirit and acid, *e.g.*, methylated spirit with a drop or two of hydrochloric acid added, also various oils, *e.g.*, aniline, clove, etc. In most cases about thirty drops of acetic acid in a bowl of water will be sufficient to remove the excess of stain from over-stained films and sections. More of the acid may, of course, be added if necessary.

Hot water also decolorises to a certain extent; over-stained films can often be readily decolorised by placing a drop of water on the film and heating gently over a flame.

When preparations have been sufficiently decolorised by an acid, they should be well washed in tap water, or in distilled water with a little lithium carbonate added.

Different organisms take up and retain the stains with various degrees of intensity, and thus duration of staining and decolorising must be modified accordingly. We sometimes have to deal

with bacteria which show a special tendency to be decolorised. This tendency can be obviated by adding a little of the stain to the alcohol, or aniline oil, employed in dehydration. In the latter case a little of the stain is rubbed down in the oil. The mixture is allowed to stand. After a little time a clear layer forms on the top with stain in solution, and this can be drawn off with a pipette.

When methylene-blue, methyl-violet, or gentian-violet is used, the stain can, after the proper degree of decolorisation has been reached, be fixed in the tissues by treating for a minute with ammonium molybdate ($2\frac{1}{2}$ per cent. in water).

The Formulæ of some of the more commonly used Stain Combinations.

1. *Löffler's Methylene-blue.*

Saturated solution of methylene-blue in alcohol . . .	30 c.c.
Solution of potassium hydrate in distilled water (1–10,000) .	100 ,,

(This dilute solution may be conveniently made by adding 1 c.c. of a 1 per cent. solution to 99 c.c. of water.)

Sections may be stained in this mixture for from a quarter of an hour to several hours. They do not readily overstain. The tissue containing the bacteria is then decolorised if necessary with $\frac{1}{2}$–1 per cent. acetic acid, till it is a pale blue-green. The section is washed in water, rapidly dehydrated with alcohol or aniline oil, cleared in xylol, and mounted.

The tissue may be contrast-stained with eosin. If this is desired, after decolorisation wash with water, place for a few seconds in 1 per cent. solution of eosin in absolute alcohol, rapidly complete dehydration with pure absolute alcohol, and proceed as before.

Films may be stained with Löffler's blue by five minutes' exposure or longer in the cold. They usually do not require decolorisation, as the tissue elements are not overstained.

2. *Kühne's Methylene-blue.*

Methylene-blue . . .	1·5 grm.
Absolute alcohol . . .	10 c.c.
Carbolic acid solution (1–20) . .	100 ,,

Stain and decolorise as with Löffler's blue, or decolorise with very weak hydrochloric acid (a few drops in a bowl of water).

3. *Carbol-Thionin-blue.*—Make up a stock solution consisting of 1 gramme of thionin-blue dissolved in 100 c.c. carbolic acid solution (1–40). For use, dilute one volume with three of water, and filter. Stain sections for five minutes or upwards. Wash very thoroughly with water, otherwise a deposit of crystals may occur in the subsequent stages. Decolorise with very weak acetic acid. A few drops of the acid added to a bowl of water are quite sufficient. Wash again thoroughly with water. Dehydrate with absolute alcohol. Thionin-blue stains more deeply than methylene-blue, and gives equally good differentiation. It is very suitable for staining typhoid and glanders bacilli in sections. Cover-glass preparations stained by this method do not usually require decolorisation. As a contrast stain, 1 per cent. watery solution of eosin may be used before staining with the thionin.

4. *Gentian-violet in Aniline Oil Water.*—Two solutions have here to be made up. (*a*) Aniline oil water. Add about 5 c.c. aniline oil to 100 c.c. distilled water in a flask, and shake violently till as much as possible of the oil has dissolved. Filter and keep in a covered bottle to prevent access of light. (*b*) Make a saturated solution of gentian-violet in alcohol. When the stain is to be used, 1 part of (*b*) is added to 10 parts of (*a*), and the mixture filtered. The mixture should be made not more than twenty-four hours before use. Stain sections for a few minutes; then decolorise with methylated spirit. Sometimes it is advantageous to add to the methylated spirit a little hydrochloric acid (2–3 drops to 100 c.c.). This staining solution is not so much used by itself as in Gram's method, which is presently to be described.

5. *Carbol-Gentian-violet.*—1 part of saturated alcoholic solution of gentian-violet is mixed with 10 parts of 5 per cent. solution of carbolic acid, the mixture being well shaken. It is used as No. 4.

6. *Carbol-Fuchsin* (see p. 105).—This is a very powerful stain, and, when used in the undiluted condition, ½–1 minute's staining is usually sufficient. It is better, however, to dilute with from five to ten times its volume of water and stain for a few minutes. In this form it has a very wide application. Methylated spirit with or without a few drops of acetic acid is the most convenient decolorising agent. Then dehydrate thoroughly, clear, and mount.

Gram's Method and its Modifications.—In the methods already described, the tissues, and more especially the nuclei, retain some stain when decolorisation has reached the point to which it can safely go without the bacteria themselves being affected. In the method of Gram, now to be detailed, this does not occur, for *the stain can here be removed completely from the ordinary tissues, and left only in the bacteria.* All kinds of bacteria, however, do not retain the stain in this method, and therefore in the systematic description of any species it is customary to state whether it is, or is not, stained by Gram's method—in other words, whether it is Gram-positive or Gram-negative. It must also be mentioned that some tissue elements may retain the stain as firmly as any bacteria, *e.g.*, keratinised epithelium, calcified particles, the granules of mast cells, and sometimes altered red blood corpuscles, etc.

In Gram's method the essential feature is the treating of the tissue, after staining, with a solution of iodine. This solution is spoken of as Gram's solution, and has the following composition:—

Iodine	1 part.
Potassium iodide .	2 parts.
Distilled water . .	300 ,,

The following is the method:—

1. Stain in aniline oil gentian-violet or in carbol-gentian-violet (*vide supra*) for about five minutes.

2. Without washing in water, now treat the section or film with repeated doses of Gram's solution till its colour becomes a purplish black, and allow the solution to act for 1 minute.

3. Again without washing with water, decolorise with absolute alcohol or methylated spirit till the colour has almost entirely disappeared, the tissues having only a faint violet tint. The period of time for which the alcohol is allowed to act varies in different laboratories. The best period is probably about three minutes.

4. For sections dehydrate completely, clear with xylol, and mount. In the case of film preparations of Gram-positive organisms, the specimen is simply washed in water, dried, and mounted. With films of organisms, whose reaction towards the Gram stain is unknown, a contrast stain (*vide infra*) should be used.

In stage (3) the process of decolorisation is more satisfactorily performed by using clove oil after sufficient dehydration with spirit, the clove oil being afterwards removed by xylol. As clove oil is a powerful decoloriser care is necessary in its use.

As a *contrast* stain for the tissues, carmalum or lithia carmine is used *before* staining with gentian-violet (1). As a contrast stain for bacteria which are decolorised by Gram's method, carbol-fuchsin diluted with twenty volumes of water or a saturated watery solution of Bismarck-brown may be used before stage (4); the former should not be applied for longer than a few seconds.

The following modifications of Gram's method may be given:—

1. *Weigert's Modification.*—The contrast staining of the tissues and stages (1) and (2) are performed as above.

(3) After using the iodine solution the preparation is dried by blotting and then decolorised by aniline-xylol (aniline oil 2, xylol 1).

(4) Wash well in xylol, and mount in xylol balsam. Film preparations after being washed in xylol may be dried, and thereafter dilute carbol-fuchsin may be used to stain bacteria which have been decolorised.

This modification probably gives the most uniformly successful results in the case of sections, but decolorisation by alcohol is preferable in the case of films of pus, etc.

2. *Nicolle's Modification.*—Carbol-gentian-violet is used as the stain. Treatment with iodine is carried out as above, and decolorisation is effected with a mixture of acetone (1 part) and alcohol (2 parts), or by the other methods mentioned above.

3. *Jensen's Modification.*—For this there are required: (*a*) a 0·5 per cent. solution of methyl-violet (6 B) in water; (*b*) a solution of iodine, 1 gramme; potassium iodide, 2 grammes; water, 100 c.c.; (*c*) a solution of neutral-red, 1 gramme in 1000 c.c. water, to which are added 2 c.c. of 1 per cent. acetic acid. Thin films are fixed by heat and allowed to cool; treat these with the methyl-violet for ¼–½ minute; wash the stain off with the iodine solution, and allow this to act for ½–1 minute; wash off with absolute alcohol, and treat with fresh alcohol till the necessary decolorisation is complete; wash off the alcohol with the neutral-red, and allow the counter-stain to act for ¼–½ minute; wash with water; dry with filter paper, and mount.

There is great variability in the avidity with which organisms stained by Gram retain the dye when washed with alcohol,

and sometimes difficulty is experienced in saying whether an organism does or does not stain by this method. Most bacteria are either frankly Gram-positive or frankly Gram-negative, but cases occur where an organism, usually Gram-positive or Gram-negative, tends when grown on certain media to show an opposite tendency, and sometimes an organism is met with in which the individuals in a film show slightly different reactions to the Gram stains. The commonest variation is for a Gram-positive organism to become in older cultures Gram-negative. According to Unna, the Gram stain can only be carried out with the pararosanilin group of dyes (*e.g.*, victoria blue, methyl violet, crystal violet, or gentian violet, which is a mixture of the last two). Two theories, a chemical and a physical, have been advanced to explain the reaction. According to the former, the iodine combines with the dye and links it to the bacterial protoplasm. According to the physical, the stain is deposited in the protoplasm, and is relatively slowly washed out by alcohol. The iodine penetrates Gram-positive bacteria most readily and causes a more pronounced deposit of the stain. Recent work indicates that the physical explanation is the more probable, and that differences in the capsule of the two classes of bacteria is an important factor in the reaction.

Stain for Tubercle and other Acid-fast Bacilli.—These bacilli cannot be well stained with a simple watery solution of a basic aniline dye. This fact can easily be tested by attempting to stain a film of a tubercle culture with such a solution; with the Gram method, however, a partial staining is effected. Such bacteria require a powerful stain containing a mordant, and must be exposed to the stain for a long time, or its action may be aided by a short application of heat. When once stained, however, they resist decolorising even with very powerful acids; they are therefore called "acid-fast." The smegma bacillus also resists decolorising with strong acids (p. 285), and a considerable number of other acid-fast bacilli are now known (p. 283). Any combination of gentian-violet or fuchsin with aniline oil or carbolic acid or other mordant will stain the bacilli named, but the following methods are most commonly used :—

Ziehl-Neelsen Carbol-Fuchsin Stain.

Basic fuchsin .	1 part.
Absolute alcohol . . .	10 parts.
Solution of carbolic acid (1 : 20) .	100 „

1. Place the specimen in this fluid, and having heated it till steam rises, allow it to remain there for five minutes, or allow it to remain in the cold stain for from twelve to twenty-four hours. (Films and paraffin sections are usually stained with hot stain, loose sections with cold; in hot stain the latter shrink.)

2. Decolorise with 20 per cent. solution of strong sulphuric acid, nitric acid, or hydrochloric acid, in water. In this the tissues become yellow.

3. Wash well with water. The tissues will regain a faint pink tint. If the colour is distinctly red, the decolorisation is insufficient, and the specimen must be returned to the acid. As a matter of practice, it is best to remove the preparation from the acid every few seconds and wash in water, replacing the specimen in the acid and re-washing till the proper pale pink tint is obtained. Then wash in alcohol for half a minute, and replace in water.

4. Contrast stain with a saturated watery solution of methylene-blue for half a minute, or with saturated watery Bismarck-brown for from two to three minutes.

5. Wash well with water. In the case of films, dry and mount. In the case of sections, dehydrate, clear, and mount.

Fraenkel's Modification of the Ziehl-Neelsen Stain.

Here the process is shortened by using a mixture containing both the decolorising agent and the contrast stain.

The sections or films are stained with the carbol-fuchsin as above described, and then placed in the following solution :—

Distilled water	50 parts.
Absolute alcohol . .	30 ,,
Nitric acid	20 ,,
Methylene-blue in crystals to saturation.	

They are treated with this till the red colour has quite disappeared and been replaced by blue. The subsequent stages are the same as in No. 5, *supra*.

Leprosy bacilli are stained in the same way, but are rather more easily decolorised than tubercle bacilli, and it is better to use only 5 per cent. sulphuric acid in decolorising.

In the case of specimens stained either by the original Ziehl-Neelsen method, or by Fraenkel's modification, the tubercle or leprosy bacilli ought to be bright red, and the tissue blue or brown, according to the contrast stain used. Other bacteria which may be present are also coloured with the contrast stain.

The Staining of Spores.—If bacilli containing spores are stained with a watery solution of a basic aniline dye the spores remain unstained. The spores either take up the stain less readily than the protoplasm of the bacilli, or they have a resisting envelope which prevents the stain from penetrating to the protoplasm. Like the tubercle bacilli, when once stained they retain the colour with considerable tenacity. The following is the simplest method for staining spores :—

1. Stain cover-glass films as for tubercle bacilli.
2. Decolorise with 1 per cent. sulphuric acid in water or with methylated spirit. This removes the stain from the bacilli.
3. Wash in water.
4. Stain with saturated watery methylene-blue for half a minute.
5. Wash in water, dry, and mount in balsam.

The result is that the spores are stained red, the protoplasm of the bacilli blue.

The spores of some organisms lose the stain more readily than those of others, and for staining some, methylated spirit is a sufficiently strong decolorising agent to use. If sulphuric acid stronger than 1 per cent. is used, the spores of many bacilli are readily decolorised.

Möller's Method.—The following method, recommended by Möller, is much more satisfactory than the previous. Before being stained, the films are placed in chloroform for two minutes, and then in a 5 per cent. solution of chromic acid for ½–2 minutes, the preparation being well washed after each reagent. Thereafter they are stained and decolorised as above.

The Staining of Capsules.—The following methods may be recommended in the case of capsulated bacteria :—

(*a*) *Welch's Method.*—This depends on the fact that in many cases the capsules can be fixed with glacial acetic acid.

Films when still wet are placed in this acid for a few seconds.

The superfluous acid is removed with filter-paper, and the preparation is treated with gentian-violet in aniline oil water repeatedly till all the acetic acid is removed.

Then wash with 1–2 per cent. solution of sodium chloride, and examine in the same solution.

The capsule appears as a pale violet halo around the deeply stained bacterium.

(*b*) *Hiss's Method.* — The staining solution consists of 1 part of a saturated alcoholic solution of fuchsin or gentian-violet and 19 parts of distilled water. A few drops of the stain are placed on a film, previously dried and fixed by heat, and the preparation is steamed for a few seconds over a flame. The staining solution is washed off with a 20 per cent. solution of copper sulphate, the preparation (without being washed in water) is dried between filter-papers, and when thoroughly dry is mounted in balsam. The capsules of pneumococci in exudates or growing in a fluid serum medium can be readily demonstrated by this method ; in the case of solid cultures, films should be made without any diluent, or a drop of fluid serum should be used. The method is easily applied, and gives excellent results.

(*c*) *Richard Muir's Method* (modified).

1. The film containing the bacteria must be very thin. It is dried and stained in filtered carbol-fuchsin for half a minute, the preparation being gently heated.
2. Wash slightly with spirit and then well in water.
3. Place in following mordant for a few seconds :—

Saturated solution of corrosive sublimate .	2 parts.
Tannic acid solution—20 per cent.	2 ,,
Saturated solution of potash alum .	5 ,,

4. Wash well in water.
5. Treat with methylated spirit for about a minute.

The preparation has a pale reddish appearance.

6. Wash well in water.

7. Counterstain with watery solution of ordinary methylene-blue for half a minute.

8. Dehydrate in alcohol, clear in xylol, and mount in balsam.

The bacteria are a deep crimson, and the capsules of a blue tint. The capsules of bacteria in certain culture media may be demonstrated by this method.

(*d*) Capsules can also be demonstrated by the Indian-ink method (p. 111).

The Staining of Flagella.—The staining of the flagella of bacteria is the most difficult of all bacteriological procedures, and it requires considerable practice to ensure that good results shall be obtained. Many methods have been introduced, of which the two following are very satisfactory :—

Preparation of Films. — In all the methods of staining flagella, young cultures on agar should be used, say a culture incubated for from ten to eighteen hours at 37° C. A very small portion of the growth is taken on the point of a platinum needle, and carefully mixed in a little water in a watch-glass; the amount should be such as to produce scarcely any turbidity in the water. A film is then made by placing a drop on a clean cover-glass and carefully spreading it out with the needle. It is allowed to dry in the air, and is then passed twice or thrice through a flame, care being taken not to over-heat it. The cover-glasses used should always be cleaned in the mixture of sulphuric acid and potassium bichromate described on page 91.

1. *Pitfield's Method as modified by Richard Muir.*

Prepare the following solutions :—

A. *The Mordant.*

Tannic acid, 10 per cent. watery solution, filtered .	10 c.c.
Corrosive sublimate, saturated watery solution .	5 ,,
Alum, saturated watery solution	5 ,,
Carbol-fuchsin (*vide* p. 105)	5 ,,

Mix thoroughly. A precipitate forms, which must be allowed to deposit, either by centrifugalising or simply by allowing to stand. Remove the clear fluid with a pipette, and transfer to a clean bottle. The mordant keeps well for one or two weeks.

B. *The Stain.*

Alum, saturated watery solution	10 c.c.
Gentian-violet, saturated alcoholic solution . .	2 ,,

The stain should not be more than two or three days old when used. It may be substituted in the mordant in place of the carbol-fuchsin.

The film having been prepared as above described, pour over it as much of the mordant as the cover-glass will hold. Heat gently over a flame till steam begins to rise, allow to steam for about a minute, and then wash well in a stream of running water for about two minutes. Then dry carefully over the flame, and when thoroughly dry pour on some of the stain. Heat as before, allowing to steam for about a minute, wash well in water, dry, and mount in a drop of xylol balsam.

This method has yielded the best results in our hands.

2. *Zettnow's Method.*

An emulsion of a young agar culture is made in water ; a small amount of this emulsion is brought into a large drop of water to which 1–2 loopfuls of 2 per cent. osmic acid solution have previously been added. From this mixture cover-glass films are made, allowed to dry, and then fixed by passing through a flame.

Mordant.

Solution A—	
Tannin	10 grms.
Water	200 c.c.
Solution B—	
Tartar emetic	2 grms.
Water	40 c.c.

Warm solution A to 50–60° C. and then add 36–37 c.c. of solution B, and heat till the precipitate which forms at first has dissolved. A small portion of the mixture when cooled in a test-tube should be opalescent ; if it is too opaque, add more of the tannin solution ; if it is clear, add 1 c.c. more of solution B. The mordant when heated should contain no precipitate ; any sediment which forms should be removed by filtering the hot solution through filter-paper. Place the cover-glass with film in a watch-glass and cover with excess of mordant ; then heat on a hot plate for 5–7 minutes at 100° C., allow to cool, and when the solution begins to become turbid, remove the film and rinse it thoroughly in water.

Stain.

A saturated solution of silver sulphate is prepared by shaking 2–3 grms. of silver sulphate with 200 c.c. water. Equal volumes of the saturated solution and of water are mixed in a test-tube, and commercial ethylamine (33 per cent.) solution is added drop by drop till the precipitate which forms at first is again just dissolved.

Cover the mordanted film with the stain and warm till steam rises freely ; when the margins of the film turn black, cease heating and rinse immediately in water. Dry and mount in Canada balsam.

Staining of Spirochætes in Sections.—The following impregnation methods have been applied for this purpose by Levaditi, and give excellent results :—

(*a*) *Levaditi's Original Method.*

(1) The tissues, which ought to be in thin slices, about 1 mm. in thickness, are best fixed in 10 per cent. formalin solution for twenty-four hours.

(2) They are washed for an hour in water, and then brought into 96 per cent. alcohol for twenty-four hours.

(3) They are then placed in 1·5 per cent. solution of nitrate of silver in a dark bottle, and are kept in an incubator at 37° C. for three days.

(4) They are washed in water for about twenty minutes, and are thereafter placed in the following mixture, namely :—

Pyrogallic acid, 4 parts.
Formalin, 5 parts.
Distilled water up to 100 parts.

They are kept in this mixture in a dark bottle for forty-eight hours at room temperature.

(5) They are then washed in water for a few minutes, taken through increasing strengths of alcohol, and embedded in paraffin in the usual way. The sections ought to be as thin as possible. In satisfactory preparations the spirochætes appear of an almost black colour against the pale yellow background of the tissues. The latter can be contrast-stained by weak carbol-fuchsin or by toluidin blue.

(*b*) *Levaditi's Newer Pyridin Method.*

(1) The tissues are fixed in formalin as in the previous method, are hardened in alcohol for twelve to sixteen hours, and then washed in water.

(2) They are then impregnated with a 1 per cent. solution of silver nitrate, to which 10 per cent. of pyridin puriss. is added at the time of use. The tissues are placed in the solution in a well-stoppered bottle, and are kept for two to three hours at room temperature and four to six hours at about 50° C. They are thereafter washed quickly in 10 per cent. pyridin solution.

(3) Reduction is then carried out in the following mixture, namely, a 4 per cent. solution of pyrogallic acid to which are added, at the time of use, 10 per cent. pure acetone and 15 per cent. pyridin.

(4) The tissues are then put through alcohol and xylol, and embedded in paraffin. The sections can be stained with toluidin blue or Unna's polychrome blue.

Examination of Spirochætes in Films.—The following methods may be recommended :—

(1) *Fontana's Method.*—This is a silver impregnation method, and three solutions are necessary—a fixing fluid, a mordant, and a silver solution. They are as follows :—

(*a*) Acetic acid 1 c.c., formalin 20 c.c., and water 100 c.c.

(*b*) 5 per cent. tannic acid in a 1 per cent. watery solution of carbolic acid.

(*c*) ½ per cent. solution of silver nitrate in distilled water. For use a small quantity of this is put in a test-tube, and a minute amount of ammonia solution is added till there is distinct turbidity. (If too much ammonia is added the fluid becomes clear again.)

Dried films, which should not be fixed by heat, are fixed in solution (*a*) for about a minute, the fluid being dropped on the film and renewed once or twice. The preparation is then washed thoroughly in running water, solution (*b*) is dropped on the film, heated till steam rises, and allowed to remain for about half a minute. It is again washed in water,

solution (*c*) is dropped on, heated till steam arises, and allowed to remain for another half minute. The preparation is finally washed in water and dried. The spirochætes are of a dark brown or black colour, and are easily found. This is the best method, and is easily carried out.

(2) *Indian Ink Method.*—An emulsion of indian ink of fine quality is sterilised by steaming and allowed to settle for a few days; a drop of the deposit diluted with an equal quantity of distilled water is well rubbed up and spread on a slide with a drop of the material to be examined (exudate from chancre or condyloma, scraping from congenitally affected organ, etc.). The film is dried and examined with an immersion lens without the interposition of a cover. Spirochætes, if present, stand out unstained, surrounded by the dark indian ink, and often positive results are rapidly obtained by means of it. The organisms are not so readily recognised by this method as by dark-ground illumination, and negative observations are thus less valuable.

(3) *Congo-Red Method* (Benians).—A small drop of a 2 per cent. aqueous solution of Congo red is placed on a slide, and a very small quantity of the secretion or exudate to be examined is rubbed into it with the platinum wire. The drop is then spread out into a tolerably thick film and allowed to dry. The film is then treated with a 1 per cent. solution of hydrochloric acid in absolute alcohol, and the preparation is dried in the air, or with blotting-paper, though the latter is apt to tear the film. Spirochætes and bacteria show up unstained on the dark background.

(4) *Giemsa's Method*, see p. 113.

The Romanowsky Stains.—Within recent years the numerous modifications of the Romanowsky stain have been extensively used. The dye concerned is the compound which is formed when watery solutions of medicinal methylene-blue and water-soluble eosin are brought together. This compound is insoluble in water but soluble in alcohol—the alcohol employed being methyl alcohol. The stain was originally used by Romanowsky for the malarial parasite, and its special quality is that it imparts to certain elements, such as the chromatin of this organism, a reddish-purple hue. This was at first thought to be simply due to the combination of the methylene-blue and the eosin, but it is now recognised that certain changes, such as occur in methylene-blue solutions with age, are necessary. In the modern formulæ these changes are brought about by treatment with alkalies, especially alkaline carbonates, as was first practised by Unna in the preparation of his polychrome methylene-blue. The stains in use thus contain a mixture of methylene-blue and its derivatives in combination with eosin; the differences in these bodies and the different proportions in which they occur in individual stains account for the different effects produced on the various constituents of a cell. The underlying chemical reactions are complicated and as yet not fully understood. Thus it is not certainly known to what

particular new body the reddish hue produced in chromatin is due, but the active constituent may be methyl-violet or methyl-azure or thionin, all of which result from the action of alkali on methylene-blue. The stains are much used in staining blood-films (in which the characters of both nucleus and cytoplasm in leucocytes are beautifully brought out), in staining bacteria in tissues or exudates, the malaria parasite, trypanosomes, the pathogenic spirochætes (such as the spirochæte pallida), and protozoa generally.

The following are the chief formulæ in use :—

1. *Jenner's Stain.*—This is an excellent blood stain, but is not so good for the study of parasites as the others to be mentioned. In its preparation no alkali is used. It is made by mixing equal parts of (*a*) a 1·2 to 1·25 per cent. solution of Grübler's water-soluble eosin (yellow shade) in distilled water and (*b*) 1 per cent. Grübler's medicinal methylene-blue (also a watery solution). The mixture is allowed to stand twenty-four hours, is filtered, and the residue is dried at 55° C. ; the powder is shaken up in distilled water, filtered, washed with distilled water, and dried. Of the powder, ·5 grm. is dissolved in 100 c.c. Merck's methyl alcohol. For use a few drops are placed on the dried unfixed film for one to three minutes, the dye is poured off, and the preparation washed with distilled water till it presents a pink colour ; it is then dried between filter-paper and mounted in xylol balsam.

2. *Leishman's Stain.*—The following solutions are prepared : (*a*) to a 1 per cent. solution of medicinal methylene-blue is added ·5 per cent. sodium carbonate ; the mixture is kept at 65° C. for twelve hours, and then for ten days at room temperature (·25 per cent. formalin may be added as a preservative) ; (*b*) 1–1000 solution of eosin, extra B.A., in distilled water. Equal volumes of the two solutions are mixed and allowed to stand for six to twelve hours with occasional stirring, the precipitate is collected, filtered, washed with distilled water, and dried. For use, ·15 per cent. is dissolved in Merck's methyl alcohol ("for analysis, acetone free") as follows : The powder is placed in a clean mortar, a little of the alcohol is added and well rubbed up with a pestle ; the undissolved powder is allowed to settle and the fluid decanted into a dry bottle ; the process is repeated with fresh fractions of the solvent till practically all the stain is dissolved, and the bottle is well stoppered. The stain will keep for a long period. For the staining of films a few drops of the stain are placed on the unfixed preparation for fifteen to thirty seconds so as to cover it with a shallow layer (the stain may be conveniently spread over the film with a glass rod), and the film is tilted to and fro so as to prevent drying. This treatment efficiently fixes the film by the action of the methyl alcohol. About double the quantity of distilled water is now dropped on the film, and the stain and diluent are quickly mixed with the rod. Five minutes are now allowed for staining, the preparation being frequently tilted to prevent precipitation of the stain, and the stain is then gently washed off with distilled water. A little of the water is kept on the film for half a minute to intensify the colour contrasts in the various cells. For certain special structures, such as Schüffner's dots or Maurer's dots in the malarial parasite, a longer staining (up to one

hour) may be necessary, and in any case it is well to practise being able to control the depth of the staining effect by observation with a low-power objective. If a preparation is to be stained for a long time it must be kept covered, and if in such cases a granular deposit is formed this may be got rid of by a quick wash with absolute alcohol. If in blood films the red corpuscles appear bluish instead of pink, the colour may be restored by washing the film with acetic acid, 1–1500. The film is dried between filter-paper and mounted.

For staining sections a little modification is necessary. A paraffin section is taken into distilled water as usual, the excess of water is drained off, and a mixture of one part of stain and two parts of distilled water is placed on it. The stain is allowed to act for five to ten minutes till the tissue appears a deep Oxford blue; it is then decolorised with 1–1500 acetic acid—the effect being watched under a low-power lens. The blue begins to come out, and the process is allowed to go on till only the nuclei remain blue. The section is then washed with distilled water, rapidly dehydrated with alcohol, cleared, and mounted. If, as sometimes happens, the eosin tint be too well marked, it can be lightened by the action of 1–7000 solution of caustic soda, this being washed off whenever the desired colour has been attained.

In certain cases, *e.g.*, for the staining of old films or of trypanosomes or Leishmaniæ in sections, Leishman recommends an initial treatment of the preparation with serum. This modification is described in Appendix E.

3. *J. H. Wright's Stain.*—In this modification 1 per cent. methylene-blue (BX or Ehrlich's rectified) and ½ per cent. sodium carbonate (both in water) are mixed and placed in a Koch's steriliser for an hour. When the fluid is cold, 1–1000 solution of extra B.A. eosin is added till the mixture becomes purplish and a finely granular black precipitate appears in suspension (about 500 c.c. eosin to 100 c.c. methylene-blue solution are required); the precipitate is filtered off and dried without being washed. A saturated solution of this is made in the pure methyl alcohol; this is filtered and diluted by adding to 80 c.c. of the saturated solution 20 c.c. of methyl alcohol. The application of the stain is almost the same as with Leishman's. A few drops are placed on the preparation for a minute for fixation; water is then dropped on till a green iridescent scum appears on the top of the fluid, and staining goes on for about two minutes; the stain is then washed off with distilled water, and a little is allowed to remain on the film till differentiation is complete; the preparation is carefully dried with filter-paper, and mounted.

4. *Giemsa's Stain.* — Giemsa believes that the reddish-blue hue characteristic of the Romanowsky stain is due to the formation of methyl-azure, and he has prepared this by a method of his own under the name "Azur I." From this, by the addition of an equal part of medicinal methylene-blue, he prepares what he calls "Azur II.," and from this again by the addition of eosin he prepares "Azur II.-eosin." The latest formula for the finished stain is as follows: Azur II.-eosin, 3 gr.; Azur II., 0·8 gr.; glycerin (Merck, chemically pure), 250 gr.; methyl alcohol (Kahlbaum, I.), 250 gr. This stain has been extensively used for demonstrating spirochætes, but it can be used for any other purpose to which the Romanowsky stains are applicable. For spirochætes the following are Giemsa's directions:—

(1) Fix films in absolute alcohol for fifteen to twenty minutes, dry with filter-paper. (2) Dilute stain with distilled water—one drop of

stain to 1 c.c. water (the mixture being well shaken). (Sometimes the water is made alkaline by the addition of one drop of 1 per cent. potassium carbonate to 10 c.c. water.) (3) Stain for fifteen minutes (a longer period is often desirable, even twenty-four hours). (4) Wash in brisk stream of distilled water. (5) Drain with filter-paper, dry, and mount in Canada balsam.

Neisser's Stain.—(*a*) The following is the original method introduced by Neisser as an aid to the diagnosis of the diphtheria bacillus. Two solutions are used as follows: (*a*) 1 grm. methylene-blue (Grübler) is dissolved in 20 c.c. of 96 per cent. alcohol, and to the solution are added 950 c.c. of distilled water and 50 c.c. of glacial acetic acid; (*b*) 2 grms. Bismarck-brown (vesuvin) dissolved in a litre of distilled water. Films are stained in (*a*) for 1–3 seconds or a little longer, washed in water, stained for 3–5 seconds in (*b*), dried, and mounted. The protoplasm of the diphtheria bacillus is stained a faint brown colour, the granules a blue colour. Cultures should be grown on a serum medium and examined within 24 hours. Satisfactory results are not always obtained in the case of films prepared from membrane, etc.

(*b*) The following is Neisser's modified cresoidin method :—

1. Stain films for a few seconds in a mixture of solutions A and B, two parts of the former to one of the latter.

A.	Methylene-blue	1 part.
	Absolute alcohol	50 parts.
	Glacial acetic acid	50 ,,
	Distilled water	1000 ,,
B.	Crystal-violet (Höchst)	1 part.
	Absolute alcohol	10 parts.
	Distilled water	300 ,,

2. Wash in water, and
3. Stain in cresoidin solution (1 : 300) for a few seconds (the cresoidin should be dissolved in warm water and the solution then filtered).
4. Wash in water, dry, and mount.

Instead of cresoidin the following solution of erythrosin may be used with advantage: Saturated alcoholic solution of erythrosin, 20 parts; saturated watery solution of picric acid, 90 parts; add to the mixture precipitated calcium carbonate to excess; allow to stand for a time, shaking at intervals; filter.

Sabouraud's Method for Staining Trichophyta.—Remove the fat from the hair or epithelial squames with chloroform. Place in a test-tube with 10 per cent. formol, and warm for two or three minutes till ebullition commences. Wash well in distilled water, and stain for one minute in Sahli's blue, which is made up as follows :—

Distilled water	40 parts.
Saturated watery methylene-blue.	24 ,,
5 per cent. solution of borax in water	16 ,,

Mix the constituents. Allow to stand for a day, and filter. After staining, wash in water, dehydrate with absolute alcohol, clear in xylol, and mount in balsam.

CHAPTER IV.

METHODS OF EXAMINING THE PROPERTIES OF SERUM—PREPARATION OF VACCINES—GENERAL BACTERIOLOGICAL DIAGNOSIS—INOCULATION OF ANIMALS.

The Testing of Agglutinative and Sedimenting Properties of Serum.

In studying the properties of serum it is necessary to have the means of measuring and diluting small quantities of fluid. The simplest method is by means of 1 c.c. and ·1 c.c. pipettes, which can be got from an instrument-maker. Each pipette should be graduated in tenths, and should deliver to the end. If the original amount of fluid to be used is small, say less than ·02 c.c., it should be diluted till it has fully this volume. This may be done by drawing up the fluid in a capillary tube (a piece of quill glass-tubing drawn out in the flame being convenient for the purpose) and marking the upper limit of the fluid, the latter then being blown out in a watch-glass. Equal amounts of ·8 per cent. salt solution can be measured out with the marked tube and added till the fluid has the necessary volume. Thorough mixture is effected by drawing up the diluted serum in the quill tubing and blowing out again, this being repeated several times. Further dilutions can be made by the graduated pipettes. Where such pipettes are not available, Wright's method may be used.

Wright's Method of measuring Small Amounts of Fluids.—A Gower's 5 c.mm. hæmocytometer pipette and some pieces of quill glass-tubing are required.

A piece of quill tubing is drawn out to capillary dimensions, and the extreme tip of it is heated in a peep flame and then drawn out till it is of the thickness of a hair, though still possessing a bore. If the point be broken off this hair, and mercury be run into the tube, the metal will be caught where the tube narrows and will pass no further—in fact, though air will pass, mercury will not. Into the wide end of this tube 5 c.mm. of mercury, measured from a Gower's pipette, is run down till it will go

no further. A mark is made on the tube at the proximal end of the mercury, which is now allowed to run out, and the tube is carefully cut through at the mark. A piece of ordinary quill tubing is drawn out and broken off just below the point where narrowing has begun, the hair end of the capillary tube is slipped through the broken-off end, and the tube is fixed in position with wax as shown in the figure. A rubber nipple placed on the end of the pipette completes the apparatus. If by pressing the nipple the air be expelled from the pipette, and the end dipped under mercury, exactly 5 c.mm. will be taken up when pressure on the nipple is relaxed. Thus other tubes can be very readily calibrated by the mercury being expelled into them, and its limits marked on their bores.

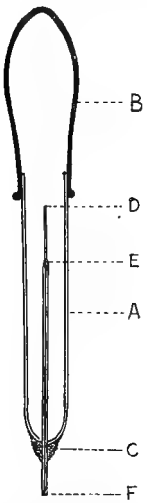

FIG. 39. — Wright's 5 c.mm. pipette. A, casing of quill tubing; B, rubber nipple; C, wax luting; E to F, capillary tube of 5 c.mm. capacity; D to E, hair capillary.

For measuring equal parts of different fluids, the pipette shown in Fig. 40, *d*, in connection with agglutination is very useful.

Methods of testing for Simple Agglutination.—By *agglutination* is meant the aggregation into clumps of uniformly disposed bacteria in a fluid; by *sedimentation* the formation of a deposit composed of such clumps when the fluid is allowed to stand. Sedimentation is thus the naked-eye evidence of agglutination. The blood serum may acquire this clumping power towards a particular organism under certain conditions,—these being chiefly met with when the individual is suffering from the disease produced by the organism, or has recovered from it, or when a certain degree of immunity has been produced artificially by injections of the organism. The nature of this property will be discussed later. Here we shall only give the technique by which the presence or absence of the property may be tested. There are two chief methods, a microscopic and a naked-eye, corresponding to the effects mentioned above. In both, the essential process is the bringing of the diluted serum into contact with the bacteria uniformly disposed in a fluid. In the former this is done on a glass slide, and the result is watched under the microscope; the occurrence of the phenomenon is shown by the aggregation of the bacteria into clumps, and if the organism is motile this change is preceded or accompanied by more or less complete loss of motility. In the latter method

the mixture is placed in an upright thin glass tube; sedimentation is shown by the formation within a given time (say from two hours at 55° C. to twenty-four hours at room temperature) of a somewhat flocculent layer at the bottom, the fluid above being clear. Two points should be attended to: (*a*) controls should always be made with normal serum and with the bacterial emulsion alone, and (*b*) the serum to be tested should never be brought in the undiluted condition into contact with the bacteria. The stages of procedure are the following:—

1. Blood is conveniently obtained by pricking the lobe of the ear, which should previously have been washed with a mixture of alcohol and ether, and allowed to dry. The blood is drawn up into a Wright's blood-capsule (Fig. 41) or into the hollow bulbous portion of a capillary pipette, such as in Fig. 40, *a*. (These pipettes can be readily made by drawing out quill glass-tubing in a flame. It is convenient always to have several ready for use.) The pipette is kept in the upright position, one end being closed. For purposes of transit, break off the bulb at the constriction and seal the ends. After the serum has separated from the coagulum the bulb is broken through near its upper end, and the serum removed by means of another capillary pipette. The serum is then to be diluted.

2. The serum may be diluted (*a*) by means of a graduated pipette—either a leucocytometer pipette (Fig. 40, *b*) or some corresponding form. In this way successive dilutions of 1 : 10, 1 : 20, 1 : 100, etc., can be rapidly made. This is the best method. (*b*) By means of a capillary pipette with a mark on the tube, the serum is drawn up to the mark and then blown out into a glass capsule; equal quantities of bouillon are successively measured in the same way, and added till the requisite dilution is obtained. (*c*) By means of a platinum needle with a loop at the end (Delépine's method). A loopful of serum is placed on a slide, and the desired number of similar loopfuls of bouillon are separately placed around on the slide. The drops are then mixed.

A very convenient and rapid method of combining the steps 1 and 2 is to draw a drop of *blood* up to the mark 1 or ·5 on a leucocytometer pipette, and draw the bouillon after it till the bulb is filled. A dilution of 10 or 20 times is thus obtained. Then blow the mixture into a U-shaped tube (Fig. 40, *c*), and centrifugalise or simply allow the red corpuscles to separate by standing. (In this method, of course, the dilution is really greater than if pure serum were used, and allowance must therefore be made in comparing results.) The presence of red corpuscles is no drawback in the case of the microscopic method, but when sedimentation tubes are used the corpuscles should be separated first.

3. The bacteria to be tested should be taken from young cultures, preferably not more than twenty-four hours old, incubated at 37° C. They may be used either as a bouillon culture or as an emulsion made by adding a small portion of an agar culture to bouillon or ·8 per cent. solution of sodium chloride. In the latter case the mass of bacteria on a platinum loop should be gently broken down at the margin of the fluid in a watch-glass. When a thick turbidity is thus obtained, any remaining fragments should first be removed, and then the organisms should be uniformly mixed with the rest of the fluid. The bacterial emulsion ought to have a faint but distinct turbidity. (When the exact degree of sediment-

ing power of a serum is to be tested—expressed as the highest dilution in which it produces complete sedimentation within twenty-four hours—a standard quantity (by weight) of bacteria must be added to a given quantity of bouillon. This is not necessary for clinical diagnosis.)

4. To test *microscopically*, mix equal quantities (measured by a marked capillary pipette) of the diluted serum and the bacterial emulsion on a glass slide, cover with a cover-glass, and examine under the microscope. The form of glass slide used for hang-drop cultures (Fig. 25) will be found very suitable. The ultimate dilution of the serum will, of course, be double the original dilution.

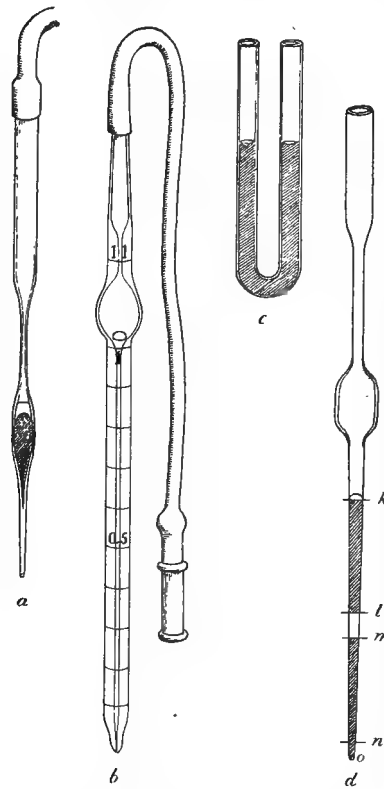

FIG. 40.—Tubes used in testing agglutinating and sedimenting properties of serum.

To observe *sedimentation*, mix equal parts of diluted serum and of bacterial emulsion, and place in a thin glass tube—a simple tube with closed end or a U-tube. Keep in upright position for twenty-four hours at room temperature, or at 55° C. in a water bath for two hours. One of Wright's sedimentation tubes is shown in Fig. 40, *d*. Diluted serum is drawn up to fill the space *mn*, a small quantity of air is sucked up after it to separate it from the bacterial emulsion, which is then drawn up in the same quantity; the diluted serum will then occupy the position *kl*. The fluids are then drawn several times up into the bulb, and returned to the capillary tube so as to mix, and finally blown carefully down close to the lower end, which is then sealed off. The sediment collects at the lower extremity.

It is often important to observe not merely the fact that agglutination occurs, but also the weakest concentration of the serum with which the reaction can be obtained.

Standard Cultures.—Dreyer has introduced a method of standardising agglutinable cultures, the organisms being killed by formalin.

The bacillus (b. typhosus, b. paratyphosus, etc.) is grown for twenty-

four hours at 37° C. in ordinary veal peptone bouillon in an Erlenmeyer flask. At the end of this time the flask is shaken and there is added to it 0·1 per cent. of commercial formalin ; it is again shaken and placed at once in a cool chamber at about 2° C. in the dark. The shaking is repeated at intervals for 4 to 5 days, the flask always being replaced in the cold chamber. At the end of three or four days the culture will be found to be sterile and will keep practically indefinitely. Such killed cultures are very suitable for sedimentation tests.

Each culture is standardised by (*a*) its opacity being brought, by dilution with normal saline containing 0·1 per cent. formalin, as nearly as possible identical with that of a "standard agglutinable culture," and (*b*) by measuring its agglutinability as compared with that of the standard culture.[1]

Measurement of Group Agglutinins.—In the case of certain groups of allied organisms,—notably the b. coli and its allies,—it has been found that when a serum clumps one member of the group it may also clump some of the allied forms. If the greatest dilution with which agglutination is obtained be estimated, the end-points for the different strains affected will be found to differ. The determination of the end-point is important, as the disease condition from which the serum is derived is generally caused by the organism which is clumped in highest dilution. In comparing the effect of a serum on different bacteria, the sedimentation method is usually employed. A series of emulsions of the different bacteria to be tested is prepared by scraping off the growth on an agar tube, and suspending in normal saline. Each of these should contain approximately the same number of bacteria per unit volume. This is attained by using emulsions of equal opacity, as judged of by noting the point at which transparency to some arbitrary standard such as a particular type or set of parallel lines ceases. A given amount of each emulsion is now mixed with different dilutions of the serum to be tested, the mixtures are all made up to the same volume, say 1 c.c., and the tubes placed at 55° C. for two or three hours. The results are then read. Dreyer takes as *standard agglutination* the highest dilution in which marked agglutination without sedimentation can be detected by the naked eye. It is often, however, an advantage to examine the results with a hand lens. Further details will be given in dealing with individual organisms.

The Absorption Method of testing Agglutinins.—This method is applied under circumstances similar to those of the last, namely, when several agglutinins acting on allied organisms are present in a serum. The principle is to remove all the agglutinins acting on one organism, and to study the properties

[1] Full details as to the use of standard cultures and sera may be had from the Department of Pathology, University of Oxford.

of those which remain. In practice, the method consists in adding to the serum an equal volume of a thick emulsion of the bacterium (the organisms being scraped off an agar slope), allowing the mixture to stand at 37° C. for two or three hours, and then separating the bacteria with the centrifuge. The supernatant clear fluid is now pipetted off, and its agglutinating properties studied on the other members of the bacterial group either by sedimentation or by the microscopic method. The object of the method is to determine which member of a bacterial group is causally related to the condition from which the serum is obtained, and examples of its application for this purpose will be found in the chapter on Typhoid Fever (p. 393). Here the principle is that, when an unknown strain belonging to such a bacterial group is under investigation, if its capacities for absorbing agglutinins from a serum are the same as those of an already recognised strain, then the two are probably identical. On the other hand, an allied strain to the organism by which the agglutinin has been produced will absorb only part of the agglutinin.

Opsonic Methods.

Method of measuring the Phagocytic Capacity of the Leucocytes.—This was first done by Leishman by a very simple method, as follows :—

Equal quantities of blood and of a fine emulsion of the bacterium to be tested are mixed together, a small drop of the mixture is placed on a glass slide and covered with a cover-glass ; the preparation is placed in the incubator at 37° C. for fifteen minutes. The cover-glass is then slipped off and the film on the slide stained by Leishman's method. A control preparation can be made with normal blood in the same way and the two films are stained as one. The number of bacteria present in, say, fifty polymorphonuclear cells successively examined is determined, and an average struck.

By this method Leishman showed that in cases of staphylococcus infection the average number of bacteria taken up was less than in a control in which the same bacterial emulsion was exposed to the blood of a healthy individual. Wright subsequently showed that phagocytosis depended upon certain substances in the serum to which he gave the name *opsonins* (*see* Immunity) and elaborated a method by which its degree could be estimated. The technique involves (1) the preparation of the bacterial emulsion, (2) the preparation of the leucocytes, (3) the preparation of samples of (*a*) serum from a normal person, and (*b*) serum from the infected person.

(1) *Preparation of Bacterial Emulsion.*—In the case of ordinary organisms, *e.g.*, the pyogenic cocci, a little of a twenty-four-hour living culture on a sloped agar tube is taken and rubbed up in a watch-glass with ·85 per cent. saline so as to obtain an emulsion consisting of single bacterial cells. With certain organisms, *e.g.*, streptococci in chains, a good deal of trituration may be necessary, and often centrifuging must be practised, for the removal of clumps. Only by experience can a knowledge be gained of the amount of culture to be used in the first instance, but the resultant emulsion usually should exhibit only the merest trace of cloudiness to the naked eye. If too strong an emulsion be used, the leucocytes may take up so many organisms that these cannot be accurately enumerated. When intensely pathogenic organisms are used, *e.g.*, b. pestis, m. melitensis, Wright recommends that the culture should be first killed by emulsifying in 40 per cent. formalin. The latter is then removed by centrifuging and the deposit washed with saline. In the case of the tubercle bacillus, Wright directs that a 7–10 day culture in glycerin broth should be sterilised by heat, collected on a filter, washed with salt solution, and dried. Ten milligrams of the dry culture should be powdered in a small agate mortar, a drop of 1 per cent. saline added, and the sticky paste triturated for about five minutes; further saline is added drop by drop till a thick emulsion is obtained of the bulk of about 1 c.c. This is centrifuged and the supernatant suspension pipetted off and diluted to the necessary degree.

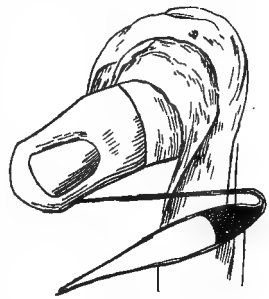

FIG. 41.—Wright's blood-capsule, and method of filling same.

(2) *Preparation of Leucocytes.*—Here the observer uses his own blood cells. A 1·5 per cent. solution of sodium citrate in ·85 per cent. sodium chloride is prepared. This is placed in a glass tube 3 inches long, made by drawing out a piece of half-inch tubing to a point, the tube being filled nearly to the brim. A handkerchief being bound round the finger, this is now pricked, and the blood allowed to flow directly into the fluid, to the bottom of which it sinks. The tube ought to be inverted between the addition of every few drops of blood, so as to bring the blood in contact with the citrate and prevent coagulation. The equivalent of about ten to twenty drops of blood should be obtained. The diluted blood is then centrifuged, and when the corpuscles are separated the supernatant fluid is removed, fresh saline is substituted, and the centrifugalisation repeated. A second washing with saline is practised, the supernatant fluid removed, and the greyish surface layer of blood, which is rich in leucocytes, removed by a fine pipette. The leucocytes may be thoroughly mixed by drawing up in a fine pipette and blowing out again, this being repeated several times.

(3) *Preparation of the Sera.*—Each sample of serum is prepared by the methods described in the case of agglutination (p. 117). If a Wright's capsule is used the blood is taken as shown in Fig. 41. The ends are sealed and the capsule is now hung by the bend on the edge of a centrifuge tube, and the serum separated by spinning the instrument. In each case serum from a normal individual should be prepared as a control.

The emulsion, corpuscles, and serum being thus prepared, an equal quantity of each is taken by a small capillary pipette, and a thorough mixture is made in the usual way. A small portion of the mixture is taken up in a capillary tube, and its ends are sealed by heat, care being taken that the contents are not overheated. The tube is then placed in the incubator at 37° for fifteen minutes. At the end of this time a drop of the mixture is placed on a slide, and a film preparation is made, this in the case of ordinary bacteria being stained by Leishman's method. With tubercle bacilli the following is the procedure: The film is fixed, washed thoroughly, stained with carbol-fuchsin as usual, decolorised with 2·5 per cent. sulphuric acid, cleared with 4 per cent. acetic acid, washed with water and counter-stained with watery solution of methylene-blue (to which ½ per cent. sodium carbonate may be added), and dried.

The two preparations are now examined microscopically with a movable stage, the number of bacteria in the protoplasm of at least a hundred polymorphonuclear leucocytes is counted, and an average per leucocyte struck; the proportion which this average in the case of the abnormal serum bears to the average in the preparation in which the healthy serum was used, constitutes the *opsonic index*—that of healthy serum being reckoned as unity.

In the case of such organisms as those of the coli-typhoid group and cholera, which are susceptible to bacteriolytic influences in the serum, it may be necessary to heat the sera of the patient and observer for half an hour at 55° C. This destroys any complement present and prevents bacteriolysis occurring. In the case of the b. typhosus the virulence of the strain employed has been shown to be an important factor.

Several modifications of Wright's technique have been suggested. For example, Simon compares not the numbers of bacteria ingested, but the percentages of cells containing bacteria and those not containing bacteria. This he calls the "percentage index," and he states that the figure thus obtained corresponds very closely to the ordinary opsonic index; he claims that the method eliminates some of the errors which may arise in the use of the ordinary technique if only a relatively small number of phagocyting cells, such as 50, be examined.

Bactericidal Methods—Deviation of Complement.

The Estimation of the Bactericidal Action of Serum.—This may be carried out by various methods, of which those of

Neisser and Wechsberg and of Wright may be given as examples. In the former, the effects of varying amounts of serum on the same amounts of bacteria are observed by means of plate cultures; in the latter, the number of bacteria which can be completely killed off by a given quantity of serum is ascertained. In carrying out experiments of this kind it is convenient to have a number of small test-tubes sterilised and plugged with cotton-wool. We can then make any required dilution of a young bacterial culture in bouillon as follows: To each of a number of tubes we add ·9 c.c. of ·8 per cent. solution of sodium chloride. To the first tube (*a*) we add ·1 c.c. of the bacterial culture, and thoroughly shake up the mixture; to the second (*b*) we add ·1 c.c. of the contents of (*a*), and shake up; to the third tube (*c*) we add ·1 c.c. of the contents of (*b*), and so on. It is thus evident that ·1 c.c. of the contents of (*a*) will correspond to ·01 c.c. and ·1 c.c. of (*b*) to ·001 c.c. of the original culture; any required fraction can thus be readily obtained. In the making of all mixtures of serum and bacteria it is essential that none of the latter shall escape the action of the former, *e.g.*, by remaining on a part of the mixing vessel with which the serum does not come in contact.

(*a*) *Method of Neisser and Wechsberg.*—A series of small plugged sterile tubes is taken, and to each we add ·5 c.c. of ·8 per cent. sodium chloride solution, and a given quantity, say $\frac{1}{5000}$ c.c., of a young bouillon culture to be tested. To the several tubes in series we then add varying amounts of the fresh serum whose action is to be observed, *e.g.*, ·2 c.c., ·1 c.c., ·05 c.c., ·025 c.c., etc. The contents of each tube are then made up to 1 c.c. with salt solution, and a few drops of sterile bouillon are added to each tube. The tubes are then well shaken and placed in the incubator at 37° C. for three hours, to allow the serum to act. (Of course several series of such tubes may be prepared and placed in the incubator for varying periods of time; we can thus observe when the bactericidal effect reaches the maximum.) At the end of the given period of time a small quantity, say ·05 c.c., of the contents of each tube is added to a tube of melted agar (cooled to about 45° C.); each agar tube is then shaken, and the contents are poured out into a sterile Petri capsule. The other tubes are similarly treated, and the Petri capsules are placed in the incubator for a suitable period of time. The number of colonies in each can then be noted. Of course gelatin can be substituted for the agar in the plates if desired.

(*b*) *Wright's Method.*—A twenty-four hours' bouillon culture is

used, and various dilutions with sterile bouillon are made according to the method described on p. 60: thus 5-, 10-, 20-, 50-, 100-, 1000-, etc., fold dilutions may be prepared. A small quantity, say 1 c.mm., of the fresh serum to be tested is mixed with an equal amount of the bacterial culture, and the mixture is placed in a small capillary tube which is sealed at the ends; similar mixtures of equal parts of serum and of each of the dilutions of culture are prepared and treated in the same way. The tubes are then placed in the incubator for eighteen to twenty-four hours at 37° C., and at the end of that time the contents of each are tested as regards sterility by means of cultures. In this way the greatest dilution in which the bacteria are completely killed off is ascertained. The number of bacteria in the original culture per c.mm. can be counted by the method given on p. 60, and thus the total number of bacteria killed off by the quantity of serum used can readily be calculated.

As will afterwards be described in greater detail (*see* chapter on Immunity), when an animal is immunised against a particular bacterium the bactericidal action of its serum may be greatly increased, and this depends on the development of a particular substance called an immune-body, which is comparatively thermostable and is not destroyed at 55° C. To analyse the bactericidal properties of such a serum, it should in the first place be heated in order to destroy the normal complement. Then to each of a series of sterile tubes we add (*a*) a quantity of normal unheated serum insufficient of itself to destroy the bacteria, (*b*) a given amount of the bacterial culture, and (*c*) varying amounts of the heated immune-serum—·1, ·01, ·001, etc., c.c. In this way we can find the quantity of the immune-serum which gives the maximum bactericidal action.

In some cases, however, when an animal is immunised against a given bacterium, or when a patient is infected with the organism, the serum may not have increased bactericidal action, but nevertheless contains an immune-body which leads to the absorption or fixation of complement. In other words, the immune-body is a substance which, along with the corresponding or homologous bacterium, binds complement (p. 127). In order, however, to explain the methods by which the fixation of complement may be demonstrated, we must first of all give some facts with regard to hæmolytic sera.

Methods of Hæmolytic Tests.—A hæmolytic serum is usually prepared by injecting the red corpuscles of an animal into the peritoneum of an animal of different species—the corpuscles of the ox or sheep are most frequently used, and the rabbit is the

most suitable animal for injection. The corpuscles ought to be completely freed of serum by repeatedly washing them in sterile salt solution, and centrifugalising. An intraperitoneal injection of the corpuscles of 5 c.c. of, say, ox's blood, followed by two injections, each of 10 c.c., at intervals of eight days, will usually give an active serum. About a week after the last injection a specimen of blood should be taken from the ear and its titre estimated. If this is satisfactory, the animal should be anæsthetised and bled from the carotid. The serum which separates may be collected in suitable lengths of quill glass-tubing drawn out at the ends, which are afterwards sealed in the flame. To ensure sterility when the serum is to be kept some time, it is advisable to heat it for an hour at 55° C. on three successive days; we have always found that serum treated in this way remains sterile. It is, of course, devoid of complement. The test amount of corpuscles is usually 1 c.c. of a 5 per cent. suspension of corpuscles in ·8 per cent. sodium chloride solution; that is, the corpuscles of 5 c.c. blood are completely freed of serum by repeatedly washing in salt solution, and then salt solution is added to make up 100 c.c. In any investigation it is necessary to obtain the minimum hæmolytic dose (M.H.D.) of the immune-body and of the complement to be used. (It is to be noted that as complement does not increase during immunisation, the hæmolytic dose of the fresh serum will come far short of representing the amount of immune-body present.) In testing the dose of immune-body, the fresh serum to be used as complement must be devoid of hæmolytic action (in the present instance rabbit's serum will be found suitable), and more than sufficient to produce lysis with immune-body is added to each of a series of tubes. Varying amounts of immune-body are added to the tubes, the contents are shaken, made up to 1·5 c.c., and incubated for two hours. The amount of lysis is then noted, and the tubes are placed in a cool chamber till next morning, when a final reading is taken. The smallest amount of immune-body which gives complete lysis is, of course, the M.H.D.: sometimes this may be as low as ·001 c.c. for the test amount of corpuscles. When further observations are to be continued on the same day, the reading after incubation must be taken as the working standard. To estimate the M.H.D. of complement, proceed in a corresponding manner; to each of a series of tubes add several doses of immune-body, and then to the several tubes different amounts of complement. The amount of complement necessary for lysis varies somewhat according to the amount of immune-body

used, being smaller with several doses of the latter than with a single dose; in estimations of the dose of complement, it is accordingly advisable to use the optimum amount of immune-body, in the present instance about five hæmolytic doses. The activity of a serum as complement varies considerably, and each sample must be separately tested.[1] The above will serve as an indication of the fundamental methods; for further details, special papers on the subject must be consulted. Corpuscles treated with sufficient immune-body to produce complete lysis on the addition of complement are usually spoken of as *sensitised corpuscles*.

The Removal of Blood-Samples from Rabbits, etc.—In such work as that just described, it is often convenient to watch the progress of an immunisation procedure by removing a sample of blood without the animal being killed. With proper care any amount of blood up to one-third of that contained in the body can be removed from the ear vein of a rabbit. The animal, which must not be flurried, is placed on a bench, and its body kept warm by being covered with a cloth. The root of the ear should be shaved over the marginal vein, the hairs on the edge of the ear should also be clipped short. It is best to have the ear dry, as the evaporation of a fluid causes contraction of the vessels. In a great deal of hæmolytic work absolute sterility of the sample is not necessary, so that washing the ear is not required. When sterile blood is desired, the precautions detailed on p. 45 may be applied. A frosted incandescent electric lamp, such as is used for microscopic illumination, is placed lighted an inch or two from the ear. The left hand of the operator should cover the animal's head in front of the ears, the thumb and index-finger being left free to compress the vein at the foot of the ear. In this way not only is the animal's eye protected from the glare of the lamp, but the distance of the latter from the ear can be regulated so as to keep it at what to the operator's hand is a pleasant warmth. In a minute or two the ear vessels will dilate, and the vein, being compressed at the root, a lateral opening is made with a bayonet-pointed surgical needle (the triangular-pointed needles supplied with the Gowers-Haldane hæmoglobinometer are also very suitable), and the blood allowed to drop into a sterile test-tube. Usually waves of contraction of the ear vessels will be observed to occur, the passing off of which must be waited for, and from time to time the clot must be gently squeezed out of the opening in the vein with the flat side of the needle, or it may be necessary slightly to enlarge the opening. The blood should be allowed to clot completely, and then, by means of a sterile platinum needle, the clot should be loosened from the sides of the tube in order that it may freely contract. The tube should be placed in the ice-chest till the following morning, when the serum can be pipetted off with a sterile, nippled pipette.

Daily samples can thus be obtained from an animal. If care be taken

[1] Complement rapidly (often within twenty-four hours) loses its strength when kept at room temperature. It can, however, be preserved for a considerable time at or near its original strength if it be kept frozen. Even if this be done, however, the strength of the complementary serum must be titred at the commencement of every experiment in which it is employed.

not to make ragged openings in the vein, often the simple removal of the previous scab will be followed by a free blood flow.

A worker associated with one of us has shown that this method can be applied in guinea-pigs, provided these be of fair size. Here successive samples of 2 c.c. can be obtained from the ear veins.

Fixation of Complement or Complement Deviation.—From the facts given above it follows that sensitised corpuscles, *i.e.*, corpuscles treated with immune-body, may be made to serve as an indicator for the presence of complement. If an antibacterial immune-body is present in a serum heated at 55° C., the serum when added to the corresponding bacterium leads to the fixation of complement, and thus prevents hæmolysis when sensitised corpuscles are added. If we represent the bacteria, or rather the receptors in the bacteria, by X, the immune-body by anti-X, and the complement by C (normal serum, say, of a guinea-pig), we may represent the method of experiment by the following scheme :—

$$X + \text{anti-}X + C \;\vdots\; + \text{sensitised corpuscles} \;\vdots$$

(The vertical dotted line represents a period of incubation for one and a half hours at 37° C.)

If lysis of the sensitised corpuscles does not occur after incubation at 37° C., then the complement has been fixed and an immune-body has been shown to be present, provided that a suitable control shows that the bacteria alone, without immune-body, do not fix sufficient complement to interfere with lysis.

This method has now been extensively used for demonstrating the presence of immune-bodies in the blood of patients suffering from a particular bacterial infection. It has also been applied to determine whether a suspected bacterium is really the cause of a disease, for if the bacterium gives with the serum of the patient deviation of complement, then there is a strong presumption that it is the infective agent (*vide* Immunity).

The Serum Diagnosis of Syphilis, Wassermann Reaction.—Wassermann, Neisser, and Bruck, proceeding in accordance with the facts established with regard to the deviation of complement, tested whether a similar phenomenon might not be obtained in the case of syphilis. For this purpose they mixed together a watery extract of syphilitic liver, rich in spirochætes (antigen), and serum from a syphilitic case (supposed to contain anti-substances), and found that a relatively large amount of complement was fixed. On the other hand, when the serum from a non-syphilitic case was substituted for the syphilitic serum, little or no fixation of complement occurred. The result was thus in accordance with expectations on theoretical grounds. Marie

and Levaditi, however, found that an extract of normal guinea-pig's liver along with syphilitic serum fixed complement, *i.e.*, acted as antigen, and subsequent observations showed that extracts of other tissues are also more or less efficient, as are also certain definite substances, such as sodium oleate, sodium glycocholate, lecithin, mixtures of such, and especially mixtures of lecithin and cholesterin, etc. Although abundant observations have established the validity of the test as a means of diagnosis, the reaction which led to its discovery is no longer sufficient to explain it, and its nature is not yet understood.

In order to carry out the test, we require (*a*) serum from the suspected case, (*b*) an extract of liver or other organ, (*c*) the fresh serum of an animal to act as complement, and (*d*) sensitised ox corpuscles, *i.e.*, a 5 per cent. suspension of washed ox corpuscles to which several doses of immune-body have been added (p. 126).

The following may be given as an example of the method as formerly used :—

Add to a small test-tube containing 0·5 c.c. of 0·8 per cent. sodium chloride solution :—(*a*) 0·05 c.c. of serum from the suspected case (heated for an hour at 55° C. to destroy the complement), (*b*) 0·1 c.c. of an extract of guinea-pig's or ox's liver, and (*c*) a certain amount, usually 0·1 c.c. of guinea-pig fresh serum to act as complement. Place in incubator at 37° C. for an hour and a half. At the end of that time add 1 c.c. of sensitised ox corpuscles and place in the incubator for another hour. If at the end of the hour the corpuscles are not lysed the complement has been fixed in the first stage—the result is *positive* as regards the presence of syphilis ; if lysis has occurred the result is *negative*. Controls were used to test effect on complement of (*a*) suspected alone and (*b*) antigen alone.

It is to be noted, however, that the substance in the syphilitic serum which leads to the fixation of complement varies greatly in amount in different cases, and it is not possible to state absolutely the quantity of complement which must be fixed in order to give a positive result. Manifestly there will be cases where the amount fixed is just under any standard adopted, and these, which are to be regarded as suspicious or doubtful, will be missed with a one-tube method. This is well exemplified in cases undergoing treatment with salvarsan. Moreover, the amount of complement, as estimated by the hæmolytic dose, varies considerably in different samples of fresh serum. It is accordingly necessary for satisfactory results to estimate the hæmolytic dose of the guinea-pig's serum, and to prepare a series of tubes, each containing the same amounts of serum and of antigen, but with a different number of doses of complement in each tube. In this way we can find the number of doses of complement deviated in each case. As controls, the effect on doses of complement

of the extract alone and of the serum alone can be tested at the same time.

Quantitative Method.—Three tubes with different doses of complement will be sufficient for routine examination.

To each of these add 0·025 c.c. of the serum to be tested (heated at 55° C.) and 0·3 c.c. of *diluted antigen* (*vide infra*).

Add to the three tubes respectively, 4, 7, and 10 doses of complement (the dose being that for 0·5 c.c. of sensitised corpuscles), and make up the amount with 0·8 per cent. saline to 0·5 c.c.

Place the tubes in the incubator for an hour at 37° C.

Then add to each 0·5 c.c. of suspension of sensitised ox corpuscles, and place again in the incubator for another hour. Place the tubes aside at the room temperature till the non-lysed corpuscles have sedimented—conveniently till next morning—and then read the results.

Controls should be made in each test as follows: one tube containing the stated amount of antigen along with 2 doses of complement and one containing the stated amount of heated serum alone with two doses of complement; to all these 0·5 c.c. of sensitised corpuscles is added after incubation for an hour. It is also advisable to put up a series with a known syphilitic serum—in routine work it is convenient to keep one from the last day's tests.

Antigen.—Various antigens have been used, but we have found that the following gives very satisfactory results:—

Take the muscle of a human heart and free it from fat; then mince it finely. Add by weight three parts of alcohol to one part of minced muscle. Allow the mixture to stand for a week or longer, shaking it up from time to time; then filter through filter-paper. For use it is to be diluted with 0·8 per cent. sodium chloride solution, usually in the proportion of one part of extract and eight parts of saline—*diluted antigen*. (It is an advantage in the case of each specimen of extract to test various dilutions of it with a known syphilitic serum and find the dilution which gives most deviation, and then to use this dilution in subsequent tests.) In diluting the extract for any test, the necessary amount of saline should be put in a test-tube and the extract run in on the top of it, the test-tube being rotated meanwhile so as to mix slowly. In this way the maximum turbidity is obtained, and this is associated with marked deviating effect.

With the amounts of extract and serum mentioned, a positive result indicating the presence of syphilis may be definitely accepted when five or more doses of complement are deviated *in addition to the amount fixed in the controls*, whereas the deviation of three doses is highly suspicious, and by some observers is accepted as a positive result. The interpretation must vary somewhat according to circumstances; for example, when a syphilitic patient is being treated the deviation of three doses would still be accepted as positive. Some observers use the same amount of complement in each tube, but vary the amounts of suspected serum, and in this way some idea of the deviating power of the serum is obtained, but we consider that the method given is to be preferred.

Lecithin-Cholesterin Method (Browning, Cruickshank, and Mackenzie).—This method depends on the fact ascertained by them, that a syphilitic serum along with lecithin plus cholesterin fixes more complement than it does along with lecithin alone, whereas this difference does not obtain in other diseases and in the normal condition. Two solutions are thus required, viz. (*a*) an alcoholic solution of lecithin[1] prepared from ox's liver, and (*b*) the same lecithin solution plus 1 per cent. of cholesterin. For use two emulsions are prepared, one part of each solution being floated on the surface of seven parts of 0·85 per cent. sodium chloride solution and then mixed slowly by rotating the tube, so as to give a turbid emulsion. For each test there are prepared a series of three tubes each containing 0·3 c.c. of lecithin-cholesterin emulsion and 0·025 c.c. of the serum to be tested, and one of two tubes, each containing 0·3 c.c. of the emulsion of lecithin alone, along with 0·025 c.c. of serum. To the former, complement is added in 4, 6, and 8 doses respectively (*i.e.*, for 0·5 c.c. sensitised corpuscles), and to the latter 2 and 4 doses. The usual controls must be made. The amount of complement absorbed in the two series is estimated, as above described. A difference of five doses is practically conclusive as to the presence of syphilis, whilst a difference of three doses is to be regarded as very suspicious. The method is a very reliable one and has the advantage of being specially delicate in the case of weakly reacting sera.

The Preparation of Vaccines.

During recent years, in consequence of the work of Sir Almroth Wright, the method of treating bacterial disease by vaccines has been very much developed. The general principle is to inject into the infected individual an emulsion of dead bacteria. In certain cases the bacteria are subjected to disintegrating processes before being used, but most frequently the vaccines simply contain killed bacterial cells, and the preparation is comparatively simple.

In the case of ordinary organisms, *e.g.*, pyogenic cocci, b. coli, etc., the growth from a young sloped agar culture is emulsified in normal saline. A uniform emulsion is necessary, and if clumps are present these must be disintegrated with a shaking-machine, or deposited by centrifuging. A sample of the living emulsion is withdrawn for the enumeration of the organisms (*vide infra*), and the vaccine is then sterilised by heating in a water bath at 57° C. for one to two hours. With certain staphylococci a longer exposure is advisable, and sometimes in such cases a higher temperature must be employed. It is probable that the lower the temperature at which the contained bacteria are killed the more efficient is the resulting vaccine. The success of the sterilisation must be tested by transferring

[1] The lecithin-cholesterin and lecithin solutions can be obtained from Messrs. Thomson, Skinner, & Hamilton, Glasgow.

some of the heated vaccine to an agar tube and incubating for twenty-four hours. Appropriate doses are then with all aseptic precautions measured by means of a sterile graduated pipette, and placed in little glass bulbs or ampoules drawn out to a capillary tube at one end. It is usual to add sufficient $\frac{1}{4}$ per cent. phenol in sterile saline to make the contents of the ampoule up to about 1 c.c. The ampoules when charged are sealed, and for use the sealed end is broken off, the contents are sucked up into a sterile hypodermic needle, and injected fairly deeply into the skin, usually in the region of the flank.

In the case of the *typhoid bacillus*, the organism is used of such virulence that a quarter of a twenty-four hours' old sloped agar culture, when administered hypodermically, will kill a guinea-pig of from 350 to 400 grams. Flasks of bouillon are inoculated with such a culture and kept for forty-two hours at 37° C. The bacteria are then killed by the flask being put into a water bath at 55° C. for twenty minutes; ·5 per cent. lysol is added, and the bacteria in the vaccine are counted.

The dosage is adjusted to the standard described in Chapter XV.

Special methods are adopted in preparing the vaccines used in connection with tuberculosis, cholera, plague, etc., and are described in the chapters on these diseases.

Methods of counting the Bacteria in Dead Cultures.—In the making of vaccines it is, as indicated above, advisable to know roughly the total number of bacterial cells, whether dead or living, present in a culture, for the dead as well as the living contain the toxins which may stimulate the therapeutic capacities of the body. A sufficiently accurate enumeration of the bacteria in a vaccine emulsion can usually be made by counting a suitably diluted sample with a Thoma-Zeiss hæmocytometer. For this purpose Zeiss supplies a special cover-glass, ground thin in the middle so that an oil immersion lens can be used. This is an advantage, but in many cases a dry lens is sufficient, especially if a small quantity of stain, *e.g.*, gentian-violet, is added to the diluent. The diluent ought also to contain some antiseptic, especially when the organisms are motile.

In MacAlister's method, the suspension of bacteria is diluted with decinormal solution of hydrochloric acid, and a drop of the mixture is placed in the counting chamber. The acid causes the organisms to deposit on the two glass surfaces and they can readily be counted in the two planes, this being carried out with dark ground illumination. A dry 7 mm. lens is used along

with a high eye-piece, *e.g.*, a Zeiss No. 18 compensating. A grating micrometer aids the enumeration.

Wright's method consists in making a mixture of blood (whose content in red blood corpuscles is known) with the bacterial culture, and comparing the number of bacteria with the number of corpuscles. The observer first estimates the red cells in his blood; a capillary pipette with a rubber nipple and with a mark near its capillary extremity is then taken, blood is sucked up to the mark, then an air-bubble, and then an equal volume of the bacterial emulsion diluted according to the empirical estimate the observer forms of its strength. The blood and bacterial emulsion are then thoroughly mixed by being drawn backwards and forwards in the wide part of the pipette, a drop is blown out on to a slide, and a blood film is spread which may be stained by Leishman's method. The bacteria and blood corpuscles are now separately enumerated in a series of fields in different parts of the preparation and the total of each added up. As the number of red corpuscles per c.mm. is known the number of bacteria can be readily calculated. In the case of certain bacteria, *e.g.*, the members of the coli-typhoid and cholera groups, when an emulsion of these is mixed with whole blood, the serum of the latter may have a bacteriolytic or an agglutinating action on the organisms, which interferes with the counting. In such cases direct enumeration, as above described, should be adopted.

Fairly accurate results, as regards number of organisms, may with practice be obtained by taking a standard opacity of emulsion, representing a known number of organisms, and diluting down with saline the emulsion of organisms to be tested till this opacity is reached. Tubes of the same diameter must of course be used, and it may be said that in a tube half an inch in diameter the lowest visible opacity in good daylight represents, in the case of cocci, approximately 100 millions per c.c. Each observer must, however, work out such standards for himself.

General Bacteriological Diagnosis.

Under this heading we have to consider the general routine which is to be observed by the bacteriologist when any material is submitted to him for examination. The object of such examination may be to determine whether any organisms are present, and if so, what organisms; or the bacteriologist may simply be asked whether a particular organism is or is not present. In any case, his inquiry must consist (1) of a micro-

scopic examination of the material submitted; (2) of an attempt to isolate the organisms present; and (3) of the identification of the organisms isolated. We must, however, before considering these points, look at a matter often neglected by those who seek a bacteriological opinion, namely, the *proper methods of obtaining and transferring to the bacteriologist the material which he is to be asked to examine.* The general principles here are (1) that every precaution must be adopted to prevent the material from being contaminated with extraneous organisms; (2) that nothing be done which may kill any organisms proper to the inquiry; and (3) that the bacteriologist obtain the material as soon as possible after it has been removed from its natural surroundings.

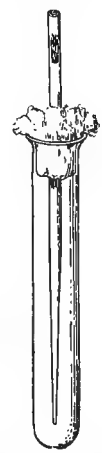

FIG. 42.—Test-tube and pipette arranged for obtaining fluids containing bacteria.

Fluids from the body cavities, pus, urine, etc., may be secured with sterile pipettes. To make one of these, take 9 inches of ordinary quill glass-tubing, draw out one end to a capillary diameter, and place a little plug of cotton wool in the other end. Insert this tube through the cotton plug of an ordinary test-tube, and sterilise by heat. To use it, remove test-tube plug with the quill tube in its centre, suck up some of the fluid into the latter, and replace in its former position in the test-tube (Fig. 42). Another method very convenient for transport is to make two constrictions on the glass tube at suitable distances, according to the amount of fluid to be taken. The fluid is drawn up into the part between the constrictions, but so as not to fill it completely. The tube is then broken through at both constrictions, and the thin ends are sealed by heating in a flame.

Solid organs to be examined should, if possible, be obtained whole. They may be treated in one of two ways. (1) The surface over one part about an inch broad is seared with a cautery heated to dull red heat. All superficial organisms are thus killed. An incision is made in this seared zone with a sterile scalpel, and small quantities of the juice are removed by a platinum spud to make cover-glass preparations and plate or smear cultures. (2) An alternative method is as follows: The surface is sterilised by soaking it well with 1 to 1000 corrosive sublimate for half an hour. It is then dried, and the

capsule of the organ is cut through with a sterile knife, the incision being further deepened by tearing. In this way a perfectly uncontaminated surface is obtained. Hints are often obtained from the clinical history of the case as to what the procedure ought to be in examination. Thus, as a matter of practice, cultures of tubercle and often of glanders bacilli can be readily obtained only by inoculation experiments.

Routine Procedure in Bacteriological Examination of Material.—In the case of a discharge regarding which nothing is known, the following procedure should be adopted: (1) Several cover-glass preparations should be made. One ought to be stained with saturated watery methylene-blue, one with a stain containing a mordant such as Ziehl-Neelsen carbol-fuchsin, one by Gram's method. (2) A series of agar smear plates or successive strokes on agar tubes (p. 58) should be made and incubated at 37° C. The clinical history, *e.g.*, where there is suspicion of pneumococcus or meningococcus infection, may suggest that special media should be employed. In every case when an unknown disease is being investigated, some of the material should be subjected to methods suitable to the growth of anaerobic bacteria. If microscopic investigation reveals the presence of bacteria, it is well to keep the material till next day, when, if no growth has appeared in the incubated agar, some other culture medium (*e.g.*, blood serum or agar smeared with blood) may be employed. If growth has taken place, say in the agar plates, one with about two hundred or fewer colonies should be made the chief basis for research. In such a plate the first question to be cleared up is: Do all the colonies present consist of the same bacterium? The shape of the colony, its size, the appearance of the margin, the graining of the substance, its colour, etc., are all to be noted. One precaution is necessary, namely, it must be noted whether the colony is on the surface of the medium or in its substance, as colonies of the same bacterium may exhibit differences according to their position. The arrangement of the bacteria in a surface colony may be still more minutely studied by means of *impression preparations*. A cover-glass is carefully cleaned and sterilised by passing quickly several times through a Bunsen flame. It is then placed on the surface of the medium, and gently pressed down on the colony. The edge is then raised by a sterile needle, it is seized with forceps, dried high over the flame, and treated as an ordinary cover-glass preparation. In this way very characteristic appearances may sometimes be noted and preserved, as in the

case of the anthrax bacillus. The colonies on a plate having been classified, a microscopic examination of each group may be made by means of cover-glass preparations, and tubes of suitable media are inoculated from each representative colony. Each of the colonies used must be marked for future reference, preferably by drawing a circle round it on the under surface of the plate or capsule with a grease pencil, a number or letter being added for easy reference.

The general lines along which observation is to be made in the case of a particular bacterium may be indicated as follows :—

1. *Microscopic Appearances.*—For ordinary descriptive purposes, young cultures, say of twenty-four hours' growth, on agar should be used, though appearances in older cultures, such as involution forms, etc., may also require attention. Note—(1) the form; (2) the size; (3) the appearance of the protoplasmic contents, especially as regards uniformity or irregularity of staining; (4) the method of grouping; (5) the staining reactions. Has it a capsule? Does the bacterium stain with simple watery solutions? Does it require the use of stains containing mordants? How does it behave towards Gram's method? It is important to investigate the first four points, both when the organism is in the fluids or tissues of the body and when growing in artificial media, as slight variations occur. It must also be borne in mind that slight variations are observed according to the kind and consistence of the medium in which the organism is growing. (6) Is it motile, and has it flagella? If so, how are they arranged? (7) Does it form spores, and if so, under what conditions as to temperature, etc.?

2. *Growth Characteristics.*—Here the most important points on which information is to be asked are : What are the characters of growth and what are the relations of growth (1) to temperature; (2) to oxygen? These can be answered from some of the following experiments :—

A. Growth on gelatin. (1) Stab culture. Note—(*a*) rate of growth; (*b*) form of growth, (*α*) on surface, (*β*) in substance; (*c*) presence or absence of liquefaction; (*d*) colour; (*e*) presence or absence of gas formation and of characteristic smell; (*f*) relation to reaction of medium. (2) Streak culture. (3) Plate cultures. Note appearances of colonies, (*a*) superficial; (*b*) deep. (4) Growth in fluid gelatin at 37° C.

B. Growth on agar at 37° C. (1) Stab. (2) Streak. Also on glycerin-agar, blood-agar, etc. Appearances of colonies in agar plates.

C. Growth in bouillon; (*a*) character of growth, (*b*) smell, (*c*) reaction, (*d*) formation of toxins.

D. Growth on special media. (1) Solidified blood serum. (2) Potatoes. (3) Lactose and other sugar media. Does fermentation occur, and is gas formed? (4) Milk. Is it curdled or turned sour? (5) Peptone solution. Is indol formed?

E. What is the viability of organism on artificial media?

3. *Results of inoculation experiments on animals.*

By attention to such points as these a considerable knowledge is attained regarding the bacterium, which will lead to its identification. In the case of many well-known organisms, however, a few of the above points taken together will often be sufficient for the recognition of the species, and experience teaches what are the essential points as regards any individual organism. In the course of the systematic description of the pathogenic organisms, it will be found that all the above points will be referred to, though not in every case.

The methods by which the morphological and biological characteristics of any growth may be observed have already been fully described. It need only be pointed out here that in giving descriptions of bacteria the greatest care must be taken to state every detail of investigation. Thus in any description of microscopic appearances the age of the growth from which the preparation was made, the medium employed, the temperature at which development took place, must be noted, along with the stain which was used; and with regard to the latter it is always preferable to employ one of the well-known staining combinations, such as Löffler's methylene-blue. Especial care is necessary in stating the size of a bacterium. The apparent size often shows slight variations dependent on the stain used and the growth conditions of the culture. Accurate measurements of bacteria can only be made by preparing microphotographs of a definite magnification, and measuring the sizes on the negatives. From these the actual sizes can easily be calculated. A rough method of estimating the size of an organism is to mix a little with a drop of the observer's blood and make a blood film. As the size of a normal red blood corpuscle is about 7·5 μ, an idea of the size of a bacterium can be obtained by comparing it with this as a standard. In describing bacterial cultures it must be borne in mind that the appearances often vary with the age. It is suggested that in the case of cultures grown at from 36° to 37° C. the appearances between twenty-four and forty-eight hours should be made the basis of description, and in the case of cultures grown between 18° and 22° C. the appearances between forty-eight and seventy-two hours should be employed. The culture fluids used must be made up and neutralised by the precise methods already described. The investigator must give every detail of the methods he has employed, in order that his observations may be capable of repetition.

In the case of a number of pathogenic organisms, identification is a comparatively easy matter. In some cases, however, great

difficulties arise in consequence of the existence of groups of organisms presenting closely allied characters, and the difficulty and importance of identification is enhanced by the fact that the same group may include both harmful and innocent members. Examples of this occurrence are found in the pyogenic cocci and their allies, in the coli-typhoid group of bacilli, and in the group of cholera vibrios. In such cases it is usually necessary to take into account all the morphological and cultural reactions of an organism before it can be adequately classified.

Inoculation of Animals.[1]

The animals generally chosen for inoculation are the mouse, the rat, the guinea-pig, the rabbit, and the pigeon. Great caution must be shown in drawing conclusions from isolated experiments on rabbits, as these animals often manifest exceptional symptoms, and are very easily killed. Dogs are, as a rule, rather insusceptible to microbic disease, and the larger animals are too expensive for ordinary laboratory purposes. In the case of the mouse and rat the variety must be carefully noted, as there are differences in susceptibility between the wild and tame varieties, and between the white and brown varieties of the latter. In the case of the wild varieties, these must be kept in the laboratory for a week or two before use, as in captivity they are apt to die from very slight causes; and, further, each individual should be kept in a separate cage, as they show great tendencies to cannibalism. Of all the ordinary animals the most susceptible to microbic disease is the guinea-pig. Practically all inoculations are performed by means of the hypodermic syringe. The best variety is that of the "Record" type, preferably furnished with platinum-iridium needles. Before use, the syringe and the needle are sterilised by boiling for five minutes. The materials used for inoculation are cultures, animal exudations, or the juice of organs. If the bacteria already exist in a fluid there is no difficulty. The syringe is most conveniently filled out of a shallow conical test-glass, which ought previously to have been covered with filter paper and sterilised. If an inoculation is to be made from organisms growing on the surface of a solid medium, either a little ought to be scraped off and shaken up in sterile bouillon or ·85 per cent. salt solution to make an emulsion, or a little sterile fluid is poured on the growth, and the latter scraped off into it. This fluid is then

[1] Experiments on animals, of course, cannot, in Britain, be performed without a licence granted by the Home Secretary.

filtered into the test-glass through a plug of sterile glass wool. This is easily effected by taking a piece of $\frac{5}{8}$-inch glass-tubing 3 inches long, drawing one end out to a fairly narrow point, plugging the tube with glass wool above the point where the narrowing commences, and sterilising by heat. By filtering an emulsion through such a pipette, flocculi which might block the needle are removed. If a solid organ or an old culture is used for inoculation, it ought to be rubbed up in a sterile quartz or metal crucible with a little sterile distilled water, by means of a sterile glass rod, and the emulsion filtered as in the last case.

The methods of inoculation generally used are: (1) by scarification of the skin; (2) by subcutaneous injection; (3) by intraperitoneal injection; (4) by intravenous injection; (5) by injections into special regions, such as the anterior chamber of the eye, the cardiac chambers, the substance of the lung, etc. Of these (2) and (3) are most frequently used. When an anæsthetic is to be administered, this is conveniently done by placing the animal, along with a piece of cotton wool or sponge soaked in chloroform, under a bell-jar or inverted glass beaker of suitable size.

1. *Scarification.*—A few parallel scratches are made in the skin of the abdomen previously cleansed, just sufficiently deep to draw blood, and the infective material is rubbed in with a platinum eyelet. The disadvantage of this method is that the inoculation is easily contaminated. The method is only occasionally used.

2. *Subcutaneous Injection.*—A hypodermic syringe is charged with the fluid to be inoculated. The hair is cut off the part to be inoculated, and the skin purified by rubbing into it some strong solution of iodine. The skin is then pinched up, and, the needle being inserted, the requisite dose is administered. The wound is sealed with a little collodion.

3. *Intraperitoneal Injection.*—The hair over the lower part of the abdomen is cut, and the skin purified with iodine. The whole thickness of the abdominal walls is then pinched up between the forefingers and thumbs of the two hands, and the needle is plunged through the fold thus formed. If the wall is then relaxed, the point of the needle will be within the abdominal cavity, and the inoculation can thus be made.

4. *Intravenous Injection.*—The vein most usually chosen is one of the auricular veins. The part has the hair removed, the skin is purified, and the vein made prominent by pressing on it between the point of inoculation and the heart. The needle is then passed obliquely into the vein, and the fluid injected. That

it has perforated the vessel will be shown by the escape of a little blood; and that the injection has taken place into the lumen of the vessel will be known by the absence of the small swelling which occurs in subcutaneous injections. If preferred, the vein may be first laid bare by snipping the skin over it. The needle is then introduced.

5. *Inoculation into the Anterior Chamber of the Eye.*—Local anæsthesia is established by applying a few drops of 2 per cent. solution of hydrochlorate of cocaine. The eye is fixed by pinching up the orbital conjunctiva with a pair of fine forceps, and, the edge of the cornea being perforated by the hypodermic needle, the injection is easily accomplished.

Sometimes inoculations are made by planting small pieces of pathological tissues in the subcutaneous tissue. This is especially done in the case of glanders and tubercle. The skin over the back is purified, and the hair cut. A small incision is made with a sterile knife, and the skin being separated from the subjacent tissues by means of the ends of a blunt pair of forceps, a little pocket is formed into which a piece of the suspected tissue is inserted. The wound is then closed with a suture, and collodion is applied. In the case of guinea-pigs, the abdominal wall is to be preferred as the site of inoculation, as the skin over the back is extremely thick.

Injections are sometimes made into other parts of the body, *e.g.*, the pleuræ, the cranium, the spinal canal. With regard to the last, Ford-Robertson has pointed out that in the rabbit it can be easily practised through the space between the seventh lumbar and first sacral vertebræ. The spine of the former lies in a line with the iliac crests. With regard to operative procedures in special regions of the body, it is unnecessary to describe these, as the application of the general principles employed above, together with those of modern aseptic surgery, will sufficiently guide the investigator as to the technique which is requisite.

After inoculation, the animals ought to be kept in comfortable cages, which must be capable of easy and thorough disinfection subsequently. For this purpose galvanised iron wire cages are the best. They can easily be sterilised by boiling them in the large fish-kettle which it is useful to have in a bacteriological laboratory for such a purpose. It is preferable to have the cages opening from above. Otherwise material which may be infective may be scratched out of the cage by the animal. The general condition of the animal is to be observed, how far it differs from the normal, whether there is increased rapidity of

breathing, etc. The temperature is usually to be taken. This is generally done *per rectum*. The thermometer (the ordinary clinical variety) is smeared with vaselin, and the bulb inserted just within the sphincter, where it is allowed to remain for a minute; it is then pushed well into the rectum for five minutes. If this precaution be not adopted a reflex contraction of the vessels may take place, which is likely to vitiate the result by giving too low a reading.

Collodion Capsules.—These have been used to allow the sojourn of bacteria within the animal body without their coming into contact with the cells of the tissues. Various substances in solution can pass in either direction through the wall by diffusion, but the wall is impermeable alike to bacteria and leucocytes. The following method of preparing such capsules is that of M'Rae modified by Harris: A gelatin capsule, such as is used by veterinary surgeons, is taken, and in one end there is fixed a small piece of thin glass tubing by gently heating the glass and inserting it. The tube becomes fixed when quite cold, and the junction is then painted round with collodion, which is allowed to dry thoroughly. The bore of the tubing is cleared of any obstructing gelatin, and the whole capsule is dipped into a solution of collodion so as to coat it completely. The collodion is allowed to dry, and the coating is repeated; it is also advisable to strengthen the layer by further painting it at the extremity and at the junction. The interior of the capsule is then filled with water by a fine capillary pipette, and the capsule is placed in hot water in order to liquefy the gelatin, which can be removed from the interior by means of the fine pipette. The sac is filled with bouillon and is placed in a tube of bouillon. It is then sterilised in the autoclave. A small quantity of the bouillon is removed, and the contents are inoculated with the particular bacterium to be studied, or an emulsion of the bacterium is added. The glass tubing is seized in sterile forceps, and is sealed off in a small flame a short distance above the junction. The closed sac ought then to be placed in a tube of sterile bouillon to test its impermeability. The result is satisfactory if no growth occurs in the surrounding medium. The sac with its contents can now be transferred to the peritoneal cavity of an animal.

Autopsies on Animals dead or killed after Inoculation.—These should be made as soon as possible after death—in fact, it is preferable to kill the animal when it shows serious signs of illness. It is necessary to have some shallow troughs, constructed either of metal or of wood covered with metal, conveni-

ently with sheet lead, and having a perforation at each corner to admit a tape or strong cord. The animal is tightly stretched out in the trough and tied in position. The size of the trough will therefore have to vary with the size of the outstretched body of the animal to be examined. In certain cases it is well to soak the surface of the animal in carbolic acid solution (1 to 20) or in corrosive sublimate (1 to 1000) before it is tied out. This not only to a certain extent disinfects the skin, but, what is more important, prevents hairs which might be affected with pathogenic products from getting into the air of the laboratory. The instruments necessary are scalpels (preferably with metal handles), dissecting forceps, and scissors. They are to be sterilised by boiling for five minutes. This is conveniently done in one of the small portable sterilisers used by surgeons. Two sets at least ought to be used in an autopsy, and they may be placed, after boiling, on a sterile glass plate covered by a bell-jar. It is also necessary to have a medium-sized hatchet-shaped cautery, or other similar piece of metal. It is well to have prepared a few freshly-drawn-out capillary tubes stored in a sterile cylindrical glass vessel, and also some larger sterile glass pipettes. The hair of the abdomen of the animal is removed. If some of the peritoneal fluid is wanted, a band should be cauterised down the linea alba from the sternum to the pubes, and another at right angles to the upper end of this; an incision should be made in the middle of these bands, and the abdominal walls thrown to each side. One or more capillary tubes should then be filled with the fluid collected in the flanks, the fluid being allowed to run up the tube and the point sealed off; or a larger quantity, if desired, is taken in a sterile pipette. If peritoneal fluid be not wanted, then an incision may be made from the episternum to the pubes, and the thorax and abdomen opened in the usual way. The organs ought to be removed with another set of instruments, and it is convenient to place them pending examination in deep Petri's capsules (sterile). It is generally advisable to make cultures and film preparations from the heart's blood. To do this, open the pericardium, sear the front of the right ventricle with a cautery, make an incision in the middle of the part seared, and remove some of the blood with a capillary tube for future examination; or, introducing a platinum eyelet, inoculate tubes and make cover-glass preparations at once. To examine any organ, sear the surface with a cautery, cut into it, and inoculate tubes and make film preparations with a platinum loop. For removing small parts of organs for making inoculations on tubes, a small platinum spud is very

useful, as the ordinary wires are apt to become bent. Place pieces of the organs in some preservative fluid for microscopic examination. The organs ought not to be touched with the fingers. When the examination is concluded, the body should have corrosive sublimate or carbolic acid solution poured over it, and be forthwith burned. The dissecting trough and all the instruments ought to be boiled for half an hour. The amount of precaution to be taken will, of course, depend on the character of the bacterium under investigation, but as a general rule every care should be used.

CHAPTER V.

BACTERIA IN AIR, SOIL, WATER, MILK. ANTISEPTICS.

As this work essentially deals with bacteriology in relation to pathology its scope does not include a full account of the applications of the science to practical sanitation. It is convenient, however, to give an outline of some of the methods employed in sanitary work and to indicate the chief results obtained.

Air.

Very little information of value can be obtained from the examination of the air, but the following are the chief methods used, along with the results obtained. More can be learned from the examination of atmospheres experimentally contaminated than by the investigation of the air as it exists under natural conditions.

Methods of Examination.—The methods employed vary with the objects in view. If it be sought to compare the relative richness of different atmospheres in organisms, and if the atmospheres in question be fairly quiescent, then it is sufficient to expose gelatin plates for definite times in the rooms to be examined. Bacteria, or the particles of dust carrying them, fall on the plates, and from the number of colonies which develop a rough idea of the richness of the air in bacteria can be obtained. Petri states that in five minutes the bacteria present in 10 litres of air are deposited on 100 square centimetres of a gelatin plate.

More complete results are available when some method is employed by which the bacteria in a given quantity of air are examined. Thus such a quantity of air may be bubbled by an aspirator through sterile water and measured amounts of this last may be plated on gelatin or other suitable medium. Of the more formal apparatus the following is to be recommended :—

Petri's Sand-Filter Method.—A glass tube open at both ends, and about 3½ inches long and half an inch wide, is taken, and in its centre is placed a transverse diaphragm of very fine iron gauze (Fig. 43, *c*) ; on each side of this is placed some fine quartz sand which has been burned, well washed, and dried to remove all impurities, and this is kept in position

by cotton plugs. The whole is sterilised by dry heat. One plug is removed, and a sterile rubber cork, *c*, inserted, through which a tube, *d*, passes to an exhausting apparatus. The tube is then clamped in an upright position in the atmosphere to be examined, with the remaining plug, *f*, uppermost. The latter is removed and the air sucked through. Difficulty may be experienced from the resistance of the sand if quick filtration be attempted. The best means to adopt is to use an air-pump —the amount of air drawn per stroke of which is accurately known—and to have a manometer (as in Fig. 26) interposed between the tube and the pump. Between each two strokes of the air-pump the mercury is allowed to return to zero. After the required amount of air has passed, the sand *a* is removed, and is distributed among a number of sterile gelatin tubes which are well shaken; plate cultures are then made, and when growth has occurred the colonies are enumerated; the sand *b* is similarly treated, and acts as a control.

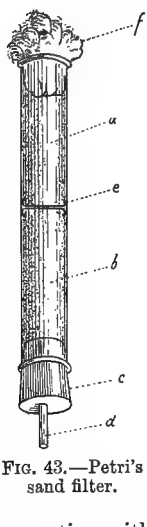

FIG. 43.—Petri's sand filter.

When it is necessary to examine air for particular organisms, special methods must often be adopted. Thus in the case of the suspected presence of tubercle bacilli a given quantity of air is drawn through a small quantity of bouillon and then injected into a guinea-pig.

Comparatively little information bearing on the harmlessness or harmfulness of the air is obtainable by the mere enumeration of the living organisms present, for under certain conditions the number may be increased by the presence of many bacteria of a purely non-pathogenic character. The organisms found in the air belong to two groups—firstly, a great variety of bacteria; secondly, yeasts and the spores of moulds and of the lower fungi. With regard to moulds, the organisms often consist of felted masses of threads, from which are thrust into the air special filaments, and in connection with these the spores are formed. By currents of air these latter can easily be detached, and may float about in a free condition. With the bacteria, on the other hand, the case is different. Usually these are growing together in little masses on organic materials, or in fluids, and it is very much by the detachment of minute particles of the substratum that the organisms become free. The entrance of bacteria into the air, therefore, is associated with conditions which favour the presence of dust, minute droplets of fluid, etc. The presence of dust, in particular, would specially favour a large number of bacteria being observed, and this is the case with the air in many industrial conditions, where the bacteria, though numerous, may be quite innocuous. Great numbers of bacteria

thus may not indicate any condition likely to injure health, and this may be true also even when the bacteria come from the crowding together of a number of healthy human beings. On the other hand, there is no doubt that disease germs can be disseminated by means of the air. The possibility of this has been shown experimentally by infecting the mouth with the b. prodigiosus, which is easily recognised by its brilliantly coloured colonies, and then studying its subsequent distribution. Most important here is the infection of the air from sick persons. The actions of coughing, sneezing, speaking, and even of deep breathing, distribute, often to a considerable distance, minute droplets of secretions from the mouth, throat, and nose, and these may float in the air for a considerable time. Even five hours after an atmosphere has been thus infected evidence may be found of bacteria still floating free. Before this time, however, most of the bacteria have settled upon various objects, where they rapidly dry, and are no longer displaceable by ordinary air currents. The diseases of known etiology where infection can thus take place are diphtheria, influenza, pneumonia, plague of the pneumonic type, and phthisis. In the case of phthisis, the deposition of tubercle bacilli has been demonstrated on cover-glasses held before the mouths of patients while talking, and animals made to breathe directly in front of such patients have become infected with tuberculosis. Apart from direct infection from individuals, pathogenic bacteria may be spread in some cases from the splashing of water infected with excreta, *e.g.*, a sewage outfall. This possibility has to be recognised especially in the cases of typhoid and cholera. Besides infection through fluid particles, infection can be caused in the air by dust coming from infected skin or clothes, etc. Flügge, from an experimental inquiry, distinguishes between large particles of dust which require an air current moving at the rate of 1 centimetre per second to keep them suspended, and the finer dust which can be kept in suspension by currents moving at from 1 to 4 millimetres per second. In the former case, when once the particles settle they cannot be displaced by currents of air except when these are moving at, at least, 5 metres per second, but the brushing, shaking, or beating of objects may, of course, distribute them. In the case of the finer dust the particles will remain for long suspended, and when they have settled can be more easily displaced, as by the waving of an arm, breathing, etc. With regard to infection by dust, a most important factor, however, is whether or not the infecting agent can preserve its vitality in a dry condition. In the case of a sporing organism such as

anthrax, vitality is preserved for long periods of time, and great resistance to drying is also possessed by the tubercle and diphtheria bacilli; but apart from such cases there is little doubt that infection is usually necessarily associated with the transport of moist particles, and is thus confined to a limited area around a sick person. Among diseases which may occasionally be thus spread, cholera and typhoid have been classed. Considerable controversy has arisen with regard to certain outbreaks of the latter disease, which have apparently been spread by dusty winds, although we have the fact that the typhoid bacillus does not survive being dried even for a short time. It appears, however, that in such epidemics the transport of infection by means of insects carried by the wind has not been entirely excluded.

As in the cases of the soil and of water, presently to be described, attempts have been made to obtain indirect evidence of the contamination of the air from human sources. Thus Gordon has shown that certain streptococci are common in the saliva; these usually correspond to the *streptococcus salivarius* (*q.v.*) of Andrewes and Horder in that they grow at 37° C., form acid and clot in litmus milk, reduce neutral-red, and ferment saccharose, lactose, and raffinose. Andrewes and Horder also describe another group,—*str. equinus*,—as common in London air, which they think is there derived from horse dung. Thus the finding of streptococci of the first group in plates exposed to air would indicate that a human source was probable, and, if the observation were made on air from the neighbourhood of a sick person, that risk of the dissemination of disease germs was present. The value of this as a practical method has yet to be determined.

Soil.

The investigation of the bacteria which may be found in the soil is undertaken from various points of view. Information may be desired as to the change its composition undergoes by a bacterial action, the result of which may be an increase in fertility and thus in economic value. Under this head may be grouped inquiries relating to the bacteria which convert ammonia and its salts into nitrates and nitrites, and to the organisms concerned in the fixation of the free nitrogen of the air. The discussion of the questions involved in such inquiries is outside the scope of the present chapter, which is more concerned with the relation of the bacteriology of the soil to questions of public health. So far as this narrower view is concerned, soil bacteria are chiefly of importance in so far as they can be washed out of the soils into potable water supplies. An important aspect of this question thus is as to the significance of certain bacteriological appearances in a water in relation to the soil from which

it has come or over which it has flowed. In this country these questions have been chiefly investigated by Houston.

Methods of Examination.—For examination of soil on surface or not far from surface, Houston recommends tin troughs 10 in. by 3 in., and pointed at one extremity, to be wrapped in layers of paper and sterilised by dry heat. If several of these be provided, then the soil can be well rubbed up and a sample secured and placed in a sterile test-tube for examination as soon as convenient after collection. If samples are to be taken at some depth beneath the surface, then a special instrument of which many varieties have been devised must be used. The general form of these is that of a gigantic gimlet stoutly made of steel. Just above the point of the instrument the shaft has in it a hollow chamber, and a sliding lateral door in this can be opened and shut by a mechanism controlled at the handle. The chamber being sterilised and closed, the instrument is bored to the required depth, the door is slid back, and by varying devices it is effected that the chamber is filled with earth; the door is reclosed and the instrument withdrawn.

In any soil the two important lines of inquiry are, first, as to the total number of organisms (usually reckoned per gramme of the fresh sample); and secondly, as to the varieties of organisms present. The number of organisms present in a soil is often, however, so enormous that it is convenient to submit only a fraction of a grm. to examination. The method employed is to weigh the tube containing the soil, shake out an amount of about the size of a bean into a litre of distilled water, and reweigh the tube. The amount placed in the water is distributed as thoroughly as possible by shaking, and, if necessary, by rubbing down with a sterile glass rod, and small quantities measured from a graduated pipette are used for investigation. For estimating the total number of organisms present in the portion of soil used, small quantities, say ·1 c.c. and 1 c.c., of the fluid are added to melted tubes of ordinary alkaline peptone gelatin; after being shaken, the gelatin is plated, incubated at 22° C., and the colonies are counted as late as the liquefaction, which always occurs round some of them, will allow. From these numbers the total number of organisms, which grow in gelatin, in a given amount of soil can be calculated.

In certain cases it may be necessary to investigate the anaerobic organisms of the soil. The inquiry is necessarily of a qualitative character and the methods to be adopted are those already described (p. 61). Sometimes information can be acquired by the injection of small portions of the soil into animals (guinea-pigs, mice).

The numbers of bacteria in the soil vary very much. According to Houston's results, fewest occur in uncultivated sandy soils, these containing on an average 100,000 per gramme. Peaty soils, though rich in organic matter, also give low results, it being possible that the acidity of such soils inhibits free bacterial growth. Garden soils yield usually about 1,500,000 bacteria per gramme, but the greatest numbers are found in soils which have been polluted by sewage, when the figures may rise to several millions. In addition to the enumeration of the numbers of bacteria present, it is a question whether something may not

be gained from a knowledge of the number of spores present in a soil relative to the total number of bacteria. This is a point which demands further inquiry, especially by the periodic investigation of examples of different classes of soils. The method is to take 1 c.c. of such a soil emulsion as that just described, add it to 10 c.c. of gelatin, heat for ten minutes at 80° C. to destroy the non-spored bacteria, plate, incubate, and count as before.

Besides the enumeration of the numbers of bacteria present in a soil, an important question in its bacteriological examination lies in inquiring what kinds of bacteria are present in any particular case. Practically this resolves itself into studying the most common bacteria present, for the complete examination of the bacterial flora of any one sample would occupy far too much time. Of these common bacteria the most important are those from whose presence indications can be gathered of the contamination of the soil by sewage, for from the public health standpoint this is by far the most important question on which bacteriology can shed light.

Bacillus mycoides.—This bacillus is 1·6 to 2·4 μ in length, and about ·9 μ in breadth. It grows in long threads which often show motility. It can be readily stained by such a combination as carbol-thionin, and retains the dye in Gram's method. All ordinary media will support its growth, and, in surface growths on agar or potato, spore formation is readily produced. Its optimum temperature is about 18° C. On gelatin plates it shows a very characteristic appearance. At first under a low power it shows a felted mass of filaments throwing out irregular shoots from the centre, and later to the naked eye these appear to be in the form of thick threads like the growth of a mould. They rapidly spread over the surface of the medium, and the whole resembles a piece of wet teased-out cotton wool. The gelatin is liquefied.

Cladothrices.—Of these several kinds are common in the soil. The ordinary *cladothrix dichotoma* is among them. This organism appears as a colourless flocculent growth with an opaque centre, and can be seen under the microscope to send out into the medium apparently branched threads which vary in thickness, being sometimes 2 μ across. They consist of rods enclosed in a sheath. These rods may divide at any point, and thus the terminal elements may be pushed along the sheath. Sometimes the sheath ruptures, and thus by the extrusion of these dividing cells and their further division the branching appearance is originated. Reproduction takes place by the formation of gonidia in the interior of the terminal cells. These gonidia acquire at one end a bundle of flagella, and for some time swim free before becoming attached and forming a new colony. Houston describes as occurring in the soil another variety, which with similar microscopic characters appears as a brownish growth with a pitted surface and diffuses a Bismarck-brown pigment into the gelatin which it liquefies.

A few experiments made with an ordinary field soil will, however, familiarise the worker with the non-pathogenic bacteria usually present. We have referred to these two because of their importance. In regard

to pathogenic organisms, especially in relation to possible sewage contamination, attention is to be directed to three groups of organisms, those resembling the b. coli, the bacillus enteritidis sporogenes, and the streptococcus pyogenes. The characters of the first of these will be found in Chapter XV., of the second in Chapter XVII., of the third in Chapter VII. For the detection of these bacteria the following procedures may be recommended :—

(*a*) *The B. coli Group.*—A third of a gramme of soil is added to 10 c.c. of bouillon, is shaken up, and loopfuls are spread on one or more plates of MacConkey's lactose neutral-red agar. After twenty-four hours' incubation in an inverted position any red colonies are picked off and subjected to the tests for the presence of b. coli detailed in Chapter XV. The presence of non-lactose fermenters (*e.g.*, b. typhosus, b. gaertner and its allies), which may have great significance, may claim attention in the examination of such plates, and the method may be employed when the detection of these organisms is the object of special inquiry.

(*b*) *The Bacillus enteritidis sporogenes.*—To search for this organism 1 grm. of the soil is thoroughly distributed in 100 c.c. sterile bouillon, and of this 1 c.c., ·1 c.c., and ·01 c.c. is added to each of three sterile milk tubes. These are heated to 80° C. for ten minutes, and then cultivated anaerobically at 37° C. for forty-eight hours. If the characteristic appearances seen in such cultures of the b. enteritidis (*g.v.*) are developed, then it may fairly safely be deduced that it is this organism which has produced them.

(*c*) *Fæcal Streptococci.*—The best method to employ is that of Prescott and Winslow modified by Mair. This depends on the fact that when b. coli and streptococci are growing together in glucose broth, as the medium becomes acid the streptococci tend to outgrow the b. coli. If lactose neutral-red agar plates be made at this stage, the colonies of streptococci, being small and intensely red, can be distinguished from the larger and paler colonies of the b. coli. They can then be picked off for investigation. It is evident that here the method must be adopted of taking as a measure of the number of streptococci present the least quantity of the original fluid in which evidence of their presence can be detected.

(*d*) *Anaerobic Bacteria.*—A soil may contain such important pathogenic agents as the b. tetani, b. œdematis maligni, etc.

We may now give in brief the results obtained by the application of such methods. First of all, uncultivated soils contain very few, if any, representatives of the b. mycoides, and this is also true to a less extent of the cladothrices. Cultivated soils, on the other hand, do practically always contain these organisms. With regard to the b. coli, its presence in a soil must be looked on as indicative of recent pollution with excremental matter. The presence of b. enteritidis is also evidence of such pollution, but from the fact that this is a sporing organism the pollution may not have been recent. With regard to the streptococci, on the other hand, the opinion is advanced that their presence is, on account of their feeble viability outside the animal body, to be looked on as evidence of extremely recent excremental pollution.

While such means have been advanced for the obtaining of indirect evidence of excremental pollution of soil, and therefore of a pollution dangerous to health from the possible presence of pathogenic organisms in excreta, investigations have also been conducted with regard to the viability in the soil of pathogenic bacteria, especially of those likely to be present in excreta, namely, the typhoid and cholera organisms. The solution of this problem is attended with difficulty, as it is not easy to identify these organisms when they are present in such bacterial mixtures as naturally occur in the soil. Now there is evidence that bacteria when growing together often influence each other's growth in an unfavourable way, so that it is only by studying the organisms in question when growing in unsterilised soils that information can be obtained as to what occurs in nature. For instance, it has been found that the b. typhosus, when grown in an organically polluted soil which has been sterilised, can maintain its vitality for fifteen weeks, but if the conditions occurring naturally be so far imitated by growing it in soil in the presence of a pure culture of a soil bacterium, it is found that sometimes the typhoid bacillus, sometimes the soil bacterium, in the course of a few weeks, or even in a few days, disappears. Further, the character of the soil exercises an important effect on the results; for instance, the typhoid bacillus soon dies out in a virgin sandy soil, even when it is the only organism present. In experiments made by sowing cultures of cholera and diphtheria in plots in a field, it was found that after, at the longest, forty days, they were no longer recognisable. Further, it is a question whether ordinary disease organisms, even if they remain alive, can multiply to any great extent in soil under natural conditions. If we are dealing with a sporing organism such as the b. anthracis, the capacity for remaining in a quiescent condition of potential pathogenicity is, of course, much greater. The most important principle to be deduced from these experiments is that the ordinary conditions of soil rather tend to be unfavourable to the continued existence of pathogenic bacteria, so that by natural processes soil tends to purify itself. It must, however, be noted that such an organism as the typhoid bacillus can exist long enough in soil to be a serious source of danger.

Water.

In the bacteriological examination of water three lines of inquiry may have to be followed. First, the number of bacteria per cubic centimetre may be estimated. Second, the kinds of

bacteria present may be investigated. Third, it may be necessary to ask if a particular organism is present, and, if so, in what number per c.c. it occurs.

Methods.—*Collection of Samples.*—In all water examinations it is preferable that the primary culture media (*i.e.*, those to which the water is actually to be added) should be inoculated at the spot at which the sample is collected. When this is not possible, the samples should be packed in sawdust and ice and the primary inoculations made as soon as possible. Otherwise the bacteria will multiply, and an erroneous idea of the number present will be obtained. Immediately after collection a slight diminution in numbers may be observed, but at any rate after six hours an increase over the initial numbers is manifest.

When samples have to be taken for transport to the laboratory, these are best collected in 8-ounce stoppered bottles, which are to be sterilised by dry heat (the stopper must be sterilised separately from the bottle and not inserted in the latter till both are cold, otherwise it will be so tightly held as to make removal very difficult).

In the case of water taken from a house tap, the water should be allowed to run for some time before the sample is taken, as water standing in pipes in a house is under very favourable conditions for multiplication of bacteria taking place, and if this precaution be not adopted an altogether erroneous idea of the number present may be obtained.

With river waters it is best to immerse the sampling bottle and then remove the stopper with forceps. Care must be taken not to touch the river bed, as the vegetable matter covering it contains many organisms. When water has to be taken from below the surface of a well or lake, a weighted sample bottle must be used. Several special bottles have been devised for such a purpose. Quite good results are obtained by tying two lengths of string to the neck and stopper of an ordinary bottle respectively, winding them round the neck and enveloping in cotton wool; any required length of string can afterwards be knotted on these. A piece of lead can be attached to the bottom of the bottle by wires passing round the neck. The whole is then wrapped in paper and sterilised. For use the bottle is carefully lowered to the required depth by the string attached to the neck, the stopper is jerked out, and the bottle filled. If the bottle and stopper be rapidly jerked through the topmost layers, contamination with surface bacteria does not appear as a serious factor.

Counting of Bacteria in Water.—This is done by adding a given quantity of water to 10 c.c. of liquefied gelatin or agar, plating, and counting the colonies which develop. The amount of water added depends on its source, and varies from ·1 c.c. of a water likely to have a high bacterial content to 5 c.c. of a purer water. It is usual to inoculate both gelatin and agar tubes. Houston recommends slight modifications in the composition of these media when they are to be used for enumerations of water bacteria. After considerable experience we can endorse his opinion as to their efficiency. The gelatin medium consists of beef broth (p. 36) 250 c.c., gelatin 120 grms., Lemco 5 grms., peptone 10 grms., water to 1000 c.c.; and the agar, of agar 20 grms., beef broth 1000 c.c., peptone 10 grms., sodium chloride 5 grms. The medium in each case is made distinctly alkaline to litmus or slightly alkaline to turmeric with 5 per cent. solution of potassium hydrate. The gelatin plates, incubated at 20° C., give an idea of the numbers of bacteria present which grow at summer heat; the agar

(which should be incubated in the inverted position), incubated at 37° C., those which grow at blood-heat. As the pathogenic and intestinal bacteria grow at this temperature, the determination of the numbers of blood-heat bacteria is important. The counts on the two media usually differ as each is favourable to the growth of its own group of organisms. In the case of both gelatin and agar plates usually forty-eight hours' incubation is allowed before the colonies are counted, but, with the former, difficulties may arise in consequence of the presence of rapidly liquefying colonies, and it may thus be necessary to count after twenty-four hours.

Probably no one medium will support the growth of all the organisms present in a given sample of water, and under certain circumstances special media must therefore be used. Thus Hansen found that in testing waters to be used in brewing it was advisable to have in the medium employed some sterile wort or beer, so that the organisms in the test experiments should be provided with the food materials which would be present in the commercial use of the water. Manifestly this principle applies generally in the bacteriological examination of waters to be used for industrial purposes.

Detection of the Presence of Special Organisms.—(a) The B. coli Group.— In ordinary public health work, it may be taken that the most frequent and important inquiry with regard to a water is directed to the investigation of the presence or absence of the b. coli and its congeners. Here the method adopted is to determine the smallest quantity of a water which gives evidence of containing organisms of this type. In applying any method with this object in view it is, we consider, absolutely necessary that it shall be carried out at the spot at which samples are collected.

The usual method is to use as the primary culture medium one of the bile-salt preparations, of which the best is MacConkey's bile-salt lactose bouillon to which litmus has been added. In this medium the members of the b. coli group cause changes resulting in the formation of acid and gas. It is thus convenient to put the medium into Durham's fermentation tubes. In practice we employ 2-ounce cylindrical medicine bottles 4½ in. high by 1½ in. in diameter. The medium, along with the inverted test-tube, is placed in these; rubber stoppers are inserted in the mouths, and they are sterilised. It is customary to test for the presence of the organisms in any sample by adding to a series of such tubes the following quantities of the water: 50 c.c. (two samples), 20 c.c., 10 c.c., 5 c.c., 1 c.c., and, it may be, in specially suspicious waters, ·5 c.c., ·1 c.c., and even ·01 c.c. The result is estimated in terms of the smallest amount of water with which the occurrence of acid and gas formation is observed. By starting with a concentrated MacConkey's mixture, it is arranged that, when the sample is added, the resulting fluid shall be of the concentration of MacConkey's medium as ordinarily prepared. Thus, in the bottle to which the 50 c.c. sample is to be added, there are placed 10 c.c. of a six-fold concentration of MacConkey's medium. In the 20 c.c. tube, there are present 20 c.c. of a medium of double strength; in the 10 c.c. tube, 10 c.c. of a mixture of double strength; and in the 5 c.c. tube, 5 c.c. of a mixture of double strength. With smaller samples, we simply use the ordinary MacConkey's medium.

For the taking of the samples, sterile 8-ounce stoppered bottles are convenient, and for each sample it is necessary to have sterile 25 c.c., 10 c.c. (graduated to tenths), and 1 c.c. (graduated to hundredths) pipettes. The armamentarium being thus simple, there is no difficulty

in carrying out the necessary manipulations at the spot where the sample is collected.

The tubes are incubated for forty-eight hours, and it is well to read the results at the end of the first twenty-four hours also. The formation of acid and gas in the tube is usually recognised as "presumptive evidence" of the presence of members of the b. coli group, but it is usual to further investigate the bacteria giving rise to this change to determine whether they are "typical" or "atypical" b. coli. With this end in view, each bottle in which acid and gas is present is well shaken up, two or three loopfuls are placed on a plate of MacConkey's neutral red bile-salt lactose agar. These loopfuls are spread over the surface by means of a sterile spreader, made by taking a piece of glass rod and turning a portion about 2 inches long at right angles to the shaft. The plates are incubated for twenty-four hours. As typical b. coli produces acid in lactose, any colonies of such an organism are of a rosy red colour. These are then picked off, sloped agar tubes are inoculated and used for the further investigation of the properties of the bacterium isolated.

The media inoculated should be gelatin, litmus milk, neutral-red lactose bouillon, glucose broth, peptone water, dulcite peptone water, adonite peptone water, mannite peptone water, inuline peptone water, saccharose peptone water, and potato.

It is well in dealing with the neutral-red lactose agar plates to inoculate a lactose peptone water tube from all the kinds of colonies present, whether these are red or not, as MacConkey rightly points out that sometimes an organism which is really a lactose fermenter does not produce a red colour on the solid medium. There is another point to be noted here, namely, that the naked-eye appearances of colonies on lactose agar are not of value in identifying the kind of organism present.

The object of growing suspicious colonies on a range of media such as that given, is to enable typical b. coli to be recognised when present. At the present time it cannot be said that bacteriologists are in agreement as to what characters determine the type of organism most frequently found in the human intestine—this, of course, being the important point in judging of the contamination of a water supply. The subject will be more fully discussed in the chapter on Typhoid Fever. Here it may be said that for work on water two attitudes are taken up in this country. First, that of Houston, who recognises as typical qualities the following: fluorescence in neutral-red broth, production of acid and gas in lactose peptone water, production of indol, production of acid and clot in litmus milk (so-called "flaginac" reaction). Secondly, that of the English Committee of 1904, which, on the one hand, laid stress on the additional factor of non-liquefaction of gelatin, and on the other, attached less importance to the production of indol and the occurrence of fluorescence (see p. 358).

With regard to saccharose fermentation, different strains of coli of undoubted intestinal origin behave differently towards saccharose, but when saccharose is fermented the occurrence is significant, as indicating a great probability that the organism is intestinal in origin.

(*b*) *B. enteritidis sporogenes and streptococci.*—As in the case of sewage, the presence of these in a water may be sought for. The methods are those which have already been given (p. 149).

Much work has been devoted to the question of these fæcal streptococci presenting specific characters by which they could be differentiated

from other streptococci. Houston has found that the prevailing type of organism here is one which produces acid and clot in milk, reduces neutral-red, and ferments saccharose, lactose, and salicin. It corresponds to the *streptococcus fæcalis* of Andrewes and Horder. The important point in this connection is to recognise that streptococci of such a type exist in great numbers in human fæces, and that when in any circumstances fæcal contamination is suspected, the isolation of streptococci strengthens the suspicion.

With regard to the objects with which the bacteriological examination of water may be undertaken, though these may be of a purely scientific character, they usually aim at contributing to the settlement of questions relating to the potability of waters, to their use in commerce, and to the efficiency of processes undertaken for the purification of waters which have undergone pollution. The last of these objects is often closely associated with the first two, as the question so often arises whether a purification process is so efficient as to make the water again fit for use.

Water derived from any natural source contains bacteria, though, as in the case of some artesian wells and some springs, the numbers may be very small, *e.g.*, 4 to 100 per c.c. In rain, snow, and ice there are often great numbers, those in the first two being derived from the air. Great attention has been paid to the bacterial content of wells and rivers. With regard to the former, precautions are necessary in arriving at a judgment. If the water in a well has been standing for some time, multiplication of bacteria may give a high numerical count. To meet this difficulty the well ought, if practicable, to be pumped dry and then allowed to fill, in order to get at what is really the important point, namely, the bacterial content of the water entering the well. Again, if the sediment of the well has been stirred up, a high value is obtained. Ordinary wells of medium depth contain from 100 to 2000 per c.c. With regard to rivers very varied results are obtained. Moorland streams are often fairly pure. In an ordinary river the numbers present vary at different seasons of the year, whilst the prevailing temperature, the presence or absence of decaying vegetation, or of washings from land, and dilution with large quantities of pure spring water, are other important features. Thus the Franklands found the rivers Thames and Lea purest in summer, and this they attributed to the fact that in this season there is most spring water entering, and very little water as washings off land. In the case of other rivers the bacteria have been found to be fewest in winter. A great many circumstances must therefore be taken into account in dealing with

mere enumerations of water bacteria, and such enumerations are only useful when they are taken simultaneously over a stretch of river, with special reference to the sources of the water entering the river. Thus it is usually found that immediately below a sewage effluent the bacterial content rises, though in a comparatively short distance the numbers may markedly decrease, and it may be that the river as far as numbers are concerned may appear to return to its previous bacterial content. The numbers of bacteria present in rivers vary so greatly that there is little use in quoting figures, most information being obtainable by comparative enumerations before and after a given event has occurred to a particular water. Such a method is of great use in estimating the efficacy of the filter-beds of a town water-supply. These usually remove from 95 to 98 per cent. of the bacteria present, and a town supply as it issues from the filter-beds should not contain more than 100 bacteria per c.c. Again, it is found that the storage of water effects a very marked bacterial purification. Thus Houston has shown in one series of observations that while 93 per cent. of samples of raw river Lea water contained b. coli. in 1 c.c. or less, in the stored water 62 per cent. of the samples showed no b. coli to be present in 100 c.c. According to Coplans, however, the diminution is not necessarily due to the organisms being killed; the real cause may be the agglutination of the bacteria following on changes in the electric conductivity which take place in stored water. The highest counts of bacteria per c.c. are observed with sewage; for example, in the London sewage the numbers range from six to twelve millions.

Much more important than the mere enumeration of the bacteria present in a water is the question whether these include forms pathogenic to man. The most important of these is the typhoid bacillus, though the b. dysenteriæ, the organisms of the paratyphoid group, the b. enteritidis sporogenes, and, in certain circumstances, the cholera vibrio, must also be kept in mind. On account of the small numbers which may be present in a dangerous water, the direct isolation of these organisms is a matter of great difficulty (though it is possible by the methods described in Chapter XV.), and from the public health standpoint the making of their being found a criterion for the condemning of a water is impracticable. There is no doubt that, *e.g.*, the typhoid and cholera bacteria can exist for some time in water—at least this has been found to be the case when sterile water has been inoculated with these bacteria. But to what extent

the same is true when they are placed in natural conditions, which involve their living in the presence of other organisms, is unknown. In the case of such organisms we therefore seek for the presence of indirect bacteriological evidence which might point to the contamination of a water by human excreta. If this be found we deduce that the water is dangerous, as organisms from any case of intestinal disease occurring in the catchment area may find access to it. The criterion here adopted is the determination of the numbers of b. coli present in the water. Klein and Houston point out that, in crude sewage, members of the coli group are practically never fewer than 100,000 per c.c., and their detection is relatively easy by the methods to be described later. In these circumstances, all modern work tends to taking the presence of b. coli in a water as the best indirect evidence of the possibility of disease organisms of intestinal origin being likely to gain access to that water. It must, however, be at once clearly recognised that the presence of members of the coli group is only an indication, and so far as the potability of any water is concerned, evidence is wanting that these organisms, however undesirable, are under ordinary circumstances actually harmful to man.

The difficulty, however, is that (except in the case of water from artesian wells), if a sufficient quantity be taken, evidence of the presence of b. coli will always be found. This arises from the fact that the organism is as numerous in the excreta of birds and other animals as in those of man, and it is impossible in the present state of knowledge to distinguish between organisms coming from these different sources. Thus in the moorland waters so much used for urban supplies, there may be a high content of b. coli—for example, 100 or more per c.c.—without the least evidence of more than the most infinitesimal fraction of these being derived from human sources, and the consumption of such a water, even in an unfiltered condition, may be perfectly safe. On the other hand, a heavily contaminated surface well may show no b. coli. to be present. There is thus the greatest difficulty in the interpretation of bacteriological results in dealing with raw waters, and it is impossible to set up any standards of the bacteriological purity of a water based on the estimation of the numbers of b. coli present alone. In any particular case the results must be considered along with those of chemical analysis and with the inspection of the locality. The difficulty is greatest when dealing with water derived from sewage-contaminated rivers, from agricultural land, and from surface wells. With regard to the first two sources, the water

should never be used in an unfiltered condition, and with regard to the last, every case must be considered on its own merits. It may be said that under ordinary circumstances an inspection of the surroundings and an unfavourable chemical analysis are sufficient to condemn a water, even if a bacteriological examination showed the absence of b. coli in large samples; and further, if in a suspicious locality the bacteriological analysis yielded a bad result, the water ought to be condemned even if from the chemical analysis it could be passed. No principle of general application can be laid down as to what in such circumstances is to be looked on as a bad result. It is probably, however, safe to say that when excremental organisms are found in 10 c.c. or less of a water from a suspicious locality it is unsafe for human consumption.

The examination for the presence of b. coli finds its best application in determining the efficiency of a filtration process, and here it is extraordinarily delicate. While again it is difficult to lay down a standard of purity, the filtration methods in use are, if properly worked, capable of delivering an effluent which does not yield b. coli in amounts less than 100 c.c., and such a degree of efficiency should in all cases be aimed at.

In connection with the derivation of b. coli from animal sources, it may be stated that birds, especially gulls, may by defiling themselves with garbage act as carriers of human excremental bacteria to water reservoirs.

As the b. coli is fairly widespread in nature, Klein and Houston hold that valuable supporting evidence is found in the presence of the b. enteritidis sporogenes and of streptococci, both of which are probably constant inhabitants of the human intestine. The spores of the former usually number 100 per c.c. in sewage, and the presence of the latter can always be recognised in ·001 grm. of human fæces. The deductions to be drawn from the presence of these in water are the same as those to be drawn from their presence in soil.

It may be said that in water artificially polluted with sewage containing intestinal bacteria, these can be detected by bacteriological methods in mixtures from ten to a hundred times more dilute than those in which the pollution can be detected by purely chemical methods.

Bacteriology of Sewage. — It is sometimes necessary to examine the bacterial content of sewage, especially in connection with the efficiency of purification works. The main lines of inquiry are here the same as for water, and the general methods are identical, the only modification necessary being that, in

consequence of the high bacterial content, much smaller quantities of the raw material must be worked with. With regard to the numbers of bacteria in sewage, these may run from a million to ten millions or even more per c.c., and here of course the question of the presence of intestinal organisms of the coli group is of great importance. The numbers of these are large, and members of the group may be detected in ·000001 c.c. or less. The numbers present are frequently considerably reduced by purification methods, but it is to be noted that, even when such methods are most successful, b. coli may yet be present in considerable quantities. This is especially true in Britain, where sewage is much more concentrated than it apparently is in America. In the latter country, purification may yield effluents in which b. coli can be detected in only ·001 c.c. By no purification method has the production of a potable water been attained, and the high content of effluents in b. coli makes the passage of typhoid bacilli through a purification system possible.

The part which bacteria play in the purification of sewage constitutes a question of great interest, to which much attention has been directed. The methods adopted for sewage purification may be divided into two groups. In the first of these, the sewage coming from the mains is run on to a bed of gravel, clinker, or coke, on which it is allowed to stand for some hours. The effluent is then run out through the bottom of the bed, which is allowed to rest for some hours before being recharged. In a modification of this method the sewage is allowed to percolate slowly through a bed consisting of large porous objects, such as broken bricks or large pieces of coke, and here the percolation may be constant, no interval of rest being given. The bacterial processes which take place in these two methods are, however, probably closely similar. In the second, the essential feature is a preliminary treatment of the sewage in more or less closed tanks ("septic tanks"), where the conditions are supposed to be largely anaerobic. This method has been adopted at Exeter, Sutton, and Yeovil in this country, and very fully worked at in America by the State Board of Health of Massachusetts. In the explanation given of the rationale of this process, sewage is looked on as existing in three stages. (1) First of all, *fresh sewage*—the newly mixed and very varied material as it enters the main sewers. (2) Secondly, *stale sewage*—the ordinary contents of the main sewers. Here there is abundant oxygen, and as the sewage flows along there occurs by bacterial action a certain formation of

carbon dioxide and ammonia, which combine to form ammonium carbonate. This is the sewage as it reaches the purification works. Here a preliminary mechanical screening may be adopted, after which it is run into an airtight tank — the septic tank. (3) It remains there for from twenty-four to thirty-six hours, and becomes a foul-smelling fluid —the *septic sewage*. The chemical changes which take place in the septic tank are of a most complex nature. The sewage entering it contains little free oxygen, and therefore the bacteria in the tank are probably largely anaerobic, and the changes which they originate consist of the formation of comparatively simple compounds of hydrogen with carbon, sulphur, and phosphorus. As a result, there is a great reduction in the amount of organic nitrogen, of albuminoid ammonia, and of carbonaceous matter. The last is important, as the clogging of ordinary filter-beds is largely due to the accumulation of such material, and of matters generally consisting of cellulose. One further important effect is that the size of the particles of the deposited matter is decreased, and therefore it is more easily broken up in the next stage of the process. This consists of running the effluent from the septic tank on to filter-beds, preferably of coke, where a further purification process takes place. By this method there is first an anaerobic treatment, succeeded by an aerobic; in the latter the process of nitrification occurs by means of the special bacteria concerned. The results are of a satisfactory nature, there being often a marked diminution in the number of coli organisms present.

In the earlier stages of any sewage purification, there is little doubt that the albuminous material present is being split up by ordinary putrefactive bacteria. In the mains and where open systems of purification are at work, aerobic forms play the chief part, while in the closed methods anaerobic organisms are those chiefly concerned. In contact and percolating systems there is evidence that at first the purifying action of bacteria is materially furthered by physical processes. Thus Dunbar has shown that when such a substance as coke is used in a sewage filter-bed a considerable amount of the albuminous material is removed in a very few minutes by adsorption, for albumin, being of a colloidal nature, is readily deposited under such circumstances in the pores of the coke in the form of films. After a time such a filter-bed becomes clogged, but on access of oxygen being allowed, it regains its adsorptive properties—probably from the oxidation of the material adsorbed.

During this stage, as in the whole purification process, four, and it may be five, processes are at work: First, the action of

ordinary bacteria splitting up the higher albuminous molecules; secondly, the action of nitrifying bacteria building up nitrites and nitrates from ammoniacal products; thirdly, the action of denitrifying bacteria which reduce nitrates to lower gaseous oxides and to free nitrogen (the presence of which in filter-beds can be demonstrated); fourthly, the action of higher forms of vegetable and animal life; fifthly, it is possible that direct chemical oxidation of the earlier products of bacterial action may occur, and in any case the access of an abundant oxygen supply to adsorbed material hastens its destruction. It is possible, as is indicated by the work of Lorrain Smith and of Mair, that perhaps too little weight has been attached to the parts played by the two last processes specified, for in the later stages of the purification process there is a very marked diminution in the number of bacteria present in the filter. Much further work, however, is necessary before the part to be assigned to each factor in operation can be properly estimated.

Further, the details of the essentially bacterial part of the process are obscure, and the relative parts played, even in an open purification process, by aerobes on the one hand, and anaerobes on the other, are little understood. When sewage is drained off to rest a filter-bed, great quantities of oxygen are sucked in, but as to how long the bed thus remains aerated, authorities differ—some maintaining that oxidation processes persist even after the bed has been recharged, while others state that soon the oxygen in the resting bed is consumed, and its place taken by carbon dioxide and nitrogen. Certainly, at certain stages of the purification process, large amounts of free nitrogen come off the bed, but whether at such periods anaerobic bacteria are or are not in the ascendant, is not known. It is probable that, from the practical standpoint, the later stages of purification should take place with free oxidation, as when anaerobic bacteria are active at this point a very offensive effluent is produced.

Often the effluent from a sewage purification system contains as many bacteria as the sewage entering, but there is often a marked diminution. It is said by some that pathogenic bacteria do not live in sewage. The typhoid bacillus has been found to die out when placed in sewage, but it certainly can live in this fluid for a much longer period than that embraced by any purification method. Thus the constant presence of b. coli, b. enteritidis, and streptococci which has been observed in sewage effluents must here still be looked on as indicating a possible infection with the typhoid bacillus, and it is only by

great dilution and prolonged exposure to the conditions present in running water that such an effluent can become suitable for forming a part of a potable water.

Milk.

The bacteriology of milk presents two aspects. The first is the economic, which concerns the changes occurring in milk collected under ordinary conditions and which may seriously affect its composition before it reaches the consumer for domestic use. From the other or hygienic standpoint, the bacteriologist has to deal with organisms either derived from the cow or subsequently introduced which may affect the health of the consumer.

The secreting structures of the mammary gland are probably sterile, but in many cases the larger ducts of the cow's udder contain bacteria of various types which will thus be found even in milk withdrawn by a cannula. The main sources of the bacteria always found present in freshly drawn milk are the external surfaces of the udder and the hands of the milkers, and the numbers present depend upon the cleanliness of the animal and its surroundings, and of the milker. Under the most favourable conditions fresh milk contains about five hundred organisms per c.c., and this figure may rise to many thousands if cleanliness has not been observed. It has been shown in numerous experiments that the number present can be easily controlled by attention to the cleanliness of the cowhouse, by grooming the animal, and by washing the udder before milking. There is some evidence that for a short time after milk is withdrawn, a slight diminution in the bacterial content may take place. Before the milk reaches the consumer, especially in city supplies, the bacterial content of apparently fresh milk may rise to several hundred thousands or even millions of bacteria per c.c.

The organisms present chiefly belong to the group of milk-souring bacteria so widespread in nature, and thus might be supposed to have only an economic significance. To this group, however, the b. coli and its congeners also belong; unfortunately these are too frequently present in milk as it reaches the consumer, and their detection may be taken as evidence of pollution from the excreta of the cow and, to a certain extent, of the want of cleanliness of the dairy. Another organism which has a similar significance is the b. enteritidis sporogenes, and along with this may be associated the streptococci found in milk.

With regard to the last, however, the difficulty of differentiating harmless from harmful forms constitutes at present a serious factor in determining the significance to be attached to their presence.

An endeavour is sometimes made to set up standards of bacterial purity in milk, based on an enumeration by plating methods of the bacteria present, but such standards are of little practical value on account of the difficulties lying in the way of their application. Thus the conditions of collection and distribution of every supply, seasonal variations in temperature, etc., would require to be considered in determining the bacterial content which would be consistent with the non-occurrence of souring of the milk during the period between withdrawal from the cow and consumption. Given a sufficient number of properly conducted dairies, however, data to form a basis for setting up standards of bacterial purity in milk might be obtained. Thus the enumeration of a large series of samples of milk from well-kept cows would furnish an idea of the degree of bacterial contamination which is unavoidable, and a standard for milk as it leaves the dairy might be obtained. Savage is of opinion that milk from the cow ought not to contain more than one bacillus coli per c.c.; on this basis vended milk containing from 100 to 1000 per c.c. might be accepted as satisfactory. As Savage points out, by studying the growth conditions of b. coli in milk it might be possible to determine whether a milk as it reaches the consumer has come from a clean dairy. This is an example of what further inquiry might result in. At present, however, the only practicable method of securing a reasonably pure milk supply is to insist on cleanliness in the dairy.

The Souring of Milk.—Under ordinary conditions the first evidence of bacterial activity, and from the economic standpoint the most important, is the occurrence of souring due to the formation of lactic and other allied acids, and the action of these on the albuminous constituents is one of the factors in curdling. The subsequent changes vary with the bacteria present, but ultimately these lead up to putrefaction of the ordinary type. The importance of the souring of milk has caused much attention to be devoted to the process, and an enormous number of bacteria has by various observers been described. While various organisms are undoubtedly concerned, it is probable that in many cases the same organism has passed under a number of different names.

There is a general agreement that two main types occur. The first of these is the *streptococcus lacticus*, originally described by Kruse. This is

an oval coccus somewhat resembling the pneumococcus, Gram-positive, and showing little tendency to chain formation. On agar plates the colonies are small and apt to be embedded in the medium. In gelatin stabs there is rather a scanty development and no liquefaction, and the organism does not grow well either on potato on in bouillon. In milk there is considerable variation in the amount of lactic acid produced, and the curd is soft and uniform. *There is no gas production.* The organism is stated to be non-pathogenic.

The other great group of milk-souring organisms is conveniently referred to the type of the *bacterium acidi lactici* of Hüppe. This organism is a short rod which may or may not be motile and which is Gram-negative. The general opinion is that it belongs to the group of the b. coli, with the group-cultural characters of which it closely corresponds. It grows readily on the surface of agar, producing somewhat slimy colonies, and a good growth can also be obtained in gelatin (which is not liquefied), bouillon, and potato; cultures on the last are greyish or brownish in colour. In milk it produces a curd which rather readily separates from the whey, and gas formation may be observed. In a lactose medium it produces acid and gas. It has a similar action on adonit but does not ferment cane-sugar, dulcit, or inulin. The other members of the coli group to which this organism is related are the *bacillus lactis aerogenes* which Escherich first isolated from the intestinal contents of new-born infants, the bacillus of Friedländer, the bacillus neapolitanus (see Chapter XV.), and organisms of the type commonly occurring in the adult intestine. In fact MacConkey considers that such organisms are more frequently found in milk than the true Hüppe type.

In many countries having temperate climates, especially in Eastern Europe and Northern Asia, sour milk products have formed staple factors in the food of the inhabitants, *e.g.*, Koumiss, produced from mare's milk and much used in Russia; Kefir, prepared from the milk of cattle, especially of goats, in the Caucasus; and Joghurt (pronounced Yohoort), a similar product used in the Balkans. Within recent years these, and especially the last, have received much attention in consequence of Metchnikoff putting forward the view that the lactic acid-producing bacteria present in them have an important effect in preventing putrefactive changes in the intestine of those using them as a food. As a consequence, similar sour-milk products have been manufactured commercially on a large scale for consumption in more civilised communities. The chief organism supposed to be used in preparing these is the bacillus bulgaricus, derived from Joghurt. This is a bacillus sometimes reaching the length of 10 μ, Gram-positive, and difficult to cultivate, growing best on gelatin or agar media containing whey. Its chief characteristic is its capacity for producing large amounts of lactic acid. In milk the acid production is unaccompanied by gas formation, and there is no subsequent liquefaction of the casein. It is necessary to say, however, that other souring organisms are present in Joghurt, and this substance can only be made by the infection of milk with the product as prepared in the Balkans.

As already stated, there occur in milk an enormous number of bacteria of very different morphological and cultural characters with the common capacity of producing lactic and other acids, and the special qualities of any souring process probably depend

on the particular combination of bacteria present. There is considerable evidence that the occurrence of souring holds in abeyance for a time the activity of putrefactive organisms whose special characteristic is the disintegration of the proteid molecules. Many changes, which may be denominated economic diseases of milk, are due to bacteria, *e.g.*, the occurrence of ropy milk, bitter milk, and coloured milk.

Pathogenic Organisms in Milk. — From the hygienic standpoint the most important consideration is that of the conditions under which organisms pathogenic to man gain access to it. These may originate in diseased conditions occurring in the cow, or the milk may become contaminated from cases of human disease. With regard to the former, the two most important are inflammatory and suppurative disease of the udder, and tuberculosis. Amongst the organisms found in the lacteal ducts are streptococci, and though frequently these are harmless, unfortunately amongst them may be the streptococcus pyogenes, and this may cause a streptococcal mastitis, sometimes with abscess formation. The milk in such a case will contain large numbers of streptococci; it may even contain pus and blood-stained serum. There is too much evidence to show that even such milk, and at any rate milk from less acute conditions, finds its way into large milk supplies such as those sent to towns, and definite outbreaks of streptococcal sore throat and abscess in the cervical glands have actually been traced to such sources. Probably many similar cases of a sporadic kind have a like origin.

Tuberculosis in the cow is, however, the most serious danger arising from the consumption of milk. The relation of the bovine type of the tubercle bacillus to the human is discussed in Chapter X. Here it need only be said that where tubercular disease occurs in the cow's udder, tubercle bacilli will be found in the milk, and, further, that where generalised tuberculosis occurs in the animal, tubercle bacilli have been found in the milk without evidence of the udder being diseased. The importance of this observation is evident from the fact that a cow containing enormous deposits of tubercle in the lungs and peritoneum may to external inspection appear in prime condition. Great controversy has taken place as to the prevalence of tubercular disease in man traceable to the consumption of tuberculous milk, and sometimes observations made by different observers have appeared contradictory. In connection with this subject it is necessary to bear in mind that the incidence of tuberculosis in cattle, and consequently the incidence of bovine

tuberculosis in man, varies greatly in different parts of the world, the reason for this having not yet been elucidated. Further, the bovine type of the bacillus probably does not produce such a fatal type of disease in man as does the human type. From this it follows that observations as to the strain of bacillus present, made *post mortem*, must be differentiated from those based on material obtained during life. It may be stated that where much tubercular milk is consumed, the children of the community will in a very considerable proportion of cases show evidence of infection of the mesenteric glands. And again, the diseases of bones and joints and of cervical glands occurring in children will at least in certain localities often yield the bovine type of bacillus. It is manifest that even if, as is probably the case, such affections may be non-fatal, the suffering and mutilation which results cannot be overlooked. So far as present evidence goes, the occurrence of bovine infection after adolescence is relatively uncommon. It may be said that the arguments advanced in support of the view that the consumption of tuberculous milk may have the effect of immunising the individual against human infection, are at present of a purely academic nature.

Amongst other diseases it has been supposed that pathological changes in the cow's udder may be originated by the causal agent of scarlet fever and of diphtheria, and that thus human epidemics may be originated. In cases where this has been suspected, a pustular ulcerative condition in the teats has been described, but in neither disease is there definite evidence that such changes are due to the causal virus. In the case of scarlet fever, the evidence for this statement is indirect, as the nature of the virus is unknown. In diphtheria, virulent bacilli have been isolated from such lesions by G. Dean and others, but the facts rather point to a pustular eruption of other origin having been secondarily infected by the bacilli from human contacts.

Apart from disease conditions of the cow itself, milk may be a disseminating agent from being infected through being handled by those suffering from disease. The two diseases most commonly thus spread are diphtheria and typhoid fever. In the former case the bacilli have been actually isolated from the milk. With typhoid fever the chief danger lies in the milk being contaminated by a " carrier " (see Chapter XV.). Further, apart from actual disease in the cow or in those handling the milk, organisms capable of causing disease to man may gain access from external sources. The most important of these is the bacillus enteritidis sporogenes and organisms of the food-

poisoning group. The first is a normal inhabitant of the cow's intestine, but the source of the latter group is more difficult to trace. In each case serious intestinal symptoms may be caused (see Chapter XV.).

The Sterilisation of Milk.—The danger arising from milk being contaminated by disease organisms has caused much attention to be paid to the subject of their destruction before the milk is consumed. The only practical method here is sterilisation by heat, and it is fortunate that practically all the important organisms to be considered are non-sporing forms and thus are relatively easily destroyed. To obviate the development of the rather unpleasant taste caused by boiling milk, Pasteur introduced the method of heating the milk for twenty minutes to between 60° and 80° C. This usually kills all but about 5 per cent. of the organisms present and will dispose of most streptococci, the tubercle bacillus, and b. diphtheriæ. Sporing putrefactive forms, however, often survive, and unless the pasteurised milk be rapidly cooled, the action of the process as an economic preservative is largely nullified, more especially as the protective milk-souring forms are destroyed. The boiling of milk for two or three minutes will kill all harmful organisms, and although some spores may survive, this is by far the most useful sterilisation procedure on account of its easy domestic application, the consumer very soon ceasing to notice the altered taste. Boiling has been objected to on account of the destruction of certain ferments, mostly of a proteolytic nature, present in fresh milk. The value of these from a dietetic standpoint is, however, at present undefined, and the only evidence that the process of boiling is harmful lies in the fact that if very young children on an exclusively milk diet be given boiled milk alone, in a certain small number of cases scurvy results. The comparative rarity of this affection and the fact that it readily yields to simple therapeutic measures make it unworthy of consideration in face of the serious dangers to which such young children are exposed if they be supplied with ordinary milk.

Antiseptics.

The death of bacteria is judged of by the fact that, when they are placed on a suitable food medium, no development takes place. From the importance of being able to kill bacteria, an enormous amount of work has been done in the way of investigating the means of doing so by chemical means, and the bodies having such a capacity are called antiseptics. So

far as is known, the activity of these agents is limited to the killing of bacteria outside the animal body, but still even this is of high importance; in the body the scope of the use of antiseptics is, amongst other factors, determined by all of them being general protoplasmic poisons.

Methods.—These vary very much. In early inquiries the amount of an antiseptic necessary to prevent putrefaction in, *e.g.*, bouillon, urine, etc., was studied; but as bacteria vary in their powers of resistance, the method was unsatisfactory, and now an antiseptic is usually judged of by its effects on pure cultures of definite pathogenic microbes, and in the case of a sporing bacterium, the effect on both the vegetative and spore forms is investigated. The organisms most used are the staphylococcus pyogenes, streptococcus pyogenes, and the organisms of typhoid, cholera, diphtheria, and anthrax—the latter being most used for testing the action on spores. The best method to employ is to take sloped agar cultures of the test organism, scrape off the growth, and mix it up with a small amount of distilled water, filter this emulsion through a plug of sterile glass wool held in a small sterile glass funnel, add a measured quantity of this fluid to a given quantity of a solution of the antiseptic in distilled water, then after the lapse of the period of observation to remove one or two loopfuls of the mixture and place them in a great excess of culture medium; here it is preferable to use fluid agar, which is then plated and incubated. In dealing with strong solutions of chemical agents it is necessary to be sure that the culture fluid is in great excess, so that the small amount of the antiseptic which is transferred with the bacteria may be diluted far beyond the strength at which it still can have any noxious influence. Sometimes it is possible at the end of the period of observation to change the antiseptic into inert bodies by the addition of some other substance, and if the inert substances are fluid there is no objection to this proceeding; but if in the process a precipitate results, the bacteria may be carried down with the precipitate and may escape the culture test. To test the effects of antiseptics on spores Koch soaked silk threads in an emulsion of anthrax spores and dried them. These were then subjected to the action of the antiseptic, well washed in water, and laid on the surface of agar. In using this method to test the efficiency of mercuric chloride it was found necessary to break up the metallic salt with ammonium sulphide to prevent the formation on the spore case of an albuminate which protected the contents from the antiseptic action. Such an occurrence only takes place with spores, and the method given above, in which the small amount of antiseptic adhering to the bacteria is swamped in an excess of culture fluid, can safely be followed, especially when a series of antiseptics is being compared. Krönig and Paul introduced what is known as the garnet method for testing antiseptics. In this, small garnets of equal size are carefully cleaned, dipped in an emulsion of anthrax spores, and allowed to dry. They are then placed in mercuric chloride, and from time to time some are removed, gently washed, and treated with ammonium sulphide to decompose the chloride. They are then well shaken in a measured quantity of water. This is plated, and the number of anthrax colonies devoloping is counted.

Much attention has been paid to the standardisation of antiseptics, and a watery solution of carbolic acid is now generally taken as the

standard with which other antiseptics are compared. Rideal and Walker point out that 110 parts by weight of B.P. carbolic acid equal 100 parts by weight of phenol, and they recommend the following method of standardising: To 5 c.c. of a particular dilution of the disinfectant add 5 drops of a 24-hour-old bouillon culture of the organism (usually b. typhosus), which has been incubated at 37° C. Shake the mixture and make subcultures every 2½ minutes to 15 minutes. Perform a parallel series of experiments with carbolic acid, and express the comparative result in terms of the carbolic acid doing the same work.

The Action of Antiseptics.—In inquiries into the actions of antiseptics attention to a great variety of factors is necessary, especially when the object is not to compare different antiseptics with one another, but when the absolute value of any body is being investigated. Thus the medium in which the bacteria to be killed are situated is important; the more albuminous it is, the greater degree of concentration is required, and this is the reason why the action of antiseptics on bacteria in wounds is limited in degree. Again, the higher the temperature at which the action is to take place, the more dilute may the antiseptic be, or the shorter the exposure necessary for a given effect to take place. The most important factor, however, to be considered is the chemical nature of the substances employed. Chick has shown that the action of a disinfectant upon a bacterium presents close analogies with the interaction of simple chemical substances, such as an acid and an alkali. In the case of anthrax spores, during the first few minutes a great fatality occurs, after which the action of the antiseptic gradually tails off. With certain other organisms, however, such as the paratyphoid bacillus, the presence in a culture—especially in a young culture—of highly resistant forms renders the initial action of an antiseptic less marked. Chick and C. J. Martin have further investigated the effect of the presence of albuminous material in a mixture of disinfectant and bacteria in decreasing the action of the disinfectant, and consider that the latter is adsorbed by the albumin. They believe that a disinfectant in an emulsionised form is more efficient than a similar disinfectant in actual solution, because of a similar phenomenon occurring; for, just as a disinfectant may be put out of action by being adsorbed by organic particles, so when these organic particles happen to be bacteria, the adsorption process causes a greater concentration of the antiseptic round the bacterial protoplasm, and thus hastens its death.

Though nearly every substance which is not a food to the animal or vegetable body is more or less harmful to bacterial life, yet certain bodies have a more marked action than others.

Thus it may be said that the most important antiseptics are the salts of the heavy metals, certain acids, especially mineral acids, certain oxidising and reducing agents, a great variety of substances belonging to the aromatic series, and volatile oils generally. In comparing different bodies belonging to any one of these groups the chemical composition or constitution is very important, and if such comparisons are to be made, the solutions compared must be equimolecular—in other words, the action of a molecule of one body must be compared with the action of a molecule of another body. This can be done by dissolving the molecular weight in grammes in a litre of water. When this is done, important facts emerge. Thus, generally speaking, the compounds of a metal of high atomic weight are more powerful antiseptics than those of one belonging to the same series, but of a lower atomic weight. Among organic bodies, again, substances with high molecular weight are more powerful than those of low molecular weight—thus butyric alcohol is more powerful than ethylic alcohol—and important differences among the aromatic bodies are associated with their chemical constitution. Thus among the cresols the ortho- and para-bodies resemble each other in general chemical properties, and stand apart from metacresol; they also are similar in antiseptic action, and are much stronger than the meta-body. The same may be observed in other groups of ortho-, meta-, and para-bodies. Again, such a property as acidity is important in the action of a substance, and, generally speaking, the greater the avidity of an acid to combine with an alkali, the more powerful an antiseptic it is. With regard to oxidising agents and reducing agents, probably the possession of such properties has been overrated as increasing bactericidal potency. Thus in the case of such reducers as sulphurous acid and formic acid, the effect is apparently chiefly due to the fact that these substances are acids. Formic acid is much more efficient than formate of sodium. In the case of permanganate of potassium, which is usually taken as the type of oxidising agents in this connection, it can be shown that the greater amount of the oxidation which takes place when this agent is brought into contact with bacteria occurs after the organisms are killed. Apart from the chemical nature of antiseptic agents, the physical factors concerned in their solution, such as electrolytic dissociation and the number of free hydrogen ions present, are important. The part played by such factors is exemplified in the fact that a strong solution acting for a short time will have the same effect as a weaker solution acting for a longer time. From what has been said it will be realised that

the real causes of a material being an antiseptic are very obscure, and at present we can only have a remote idea of the factors at work.

The Effects of certain Antiseptics.—Here we can only briefly indicate certain results obtained with the more common members of the group.

Chlorine.—All the halogens have been found to be powerful antiseptics, but from the cheapness with which it can be produced chlorine has been most used; it is the chief active agent in the somewhat complex action of bleaching powder. Nissen, investigating the action of the latter, found that 1½ per cent. killed typhoid bacilli in fæces; and Rideal found that 1 part to 400–500 disinfected sewage in fourteen minutes, and Delépine's results show that 1 part to 50 (equal to ·66 per cent. of chlorine) rapidly kills the tubercle bacillus, and 1 part to 10 (equal to 3·3 per cent.) killed anthrax spores. Klein found that ·05 per cent. of chlorine killed most bacterial spores in five minutes.

Hypochlorous Acid and Hypochlorites.—These enter into the action of bleaching powder, and their potency as antiseptics has been long known. Recently they have been much used in connection with war-surgery. The chief preparations are the following: (1) Eusol (Lorrain Smith). This is made by dissolving 12·5 gr. good bleaching powder and 12·5 gr. boric acid in one litre of water, shaking up from time to time for two hours and filtering; this solution, while containing abundant free hypochlorous acid (about 0·26 per cent.), has, in consequence of the formation of calcium biborate, a low free hydrogen-ion concentration—it thus cannot become definitely acid and is relatively non-irritant to the tissues. (2) Dakin-Daufresne solution. 20 gr. average bleaching powder is shaken up in half a litre of water and left for six to twelve hours; 10 gr. dry sodium carbonate and 8 gr. sodium bicarbonate are dissolved in another half-litre of water and added to the bleaching powder solution; the mixture is well shaken, allowed to stand for half an hour, and the liquid is siphoned off and filtered through double filter paper. This solution contains 0·45 per cent. sodium hypochlorite and is alkaline.

Iodine is a powerful antiseptic and as Tr. Iodi is of great use in purifying the skin before surgical incision.

Iodine Terchloride.—This is a very unstable compound of iodine and chlorine, and, seeing that the substance only remains as ICl_3 in an atmosphere of chlorine gas, it is open to doubt whether the antiseptic effects attributed to it are not due to a very complicated action of free hydrochloric acid, hydriodic acid, of oxyacids of chlorine and iodine produced by its decomposition, and also, in certain cases, of organic iodine compounds formed from its contact with albuminous material. It is stated that the action is very potent: a 1 per cent. solution is said instantly to kill even anthrax spores, but if the spores be in bouillon, death occurs after from ten to twelve minutes. In serum the necessary exposure is from thirty to forty minutes. A solution of 1–1000 will kill the typhoid, cholera, and diphtheria organisms in five minutes.

Nascent Oxygen.—This is chiefly available in two ways—firstly, when in the breaking up of ozone the free third atom of the ozone molecule is seeking to unite with another similar atom; secondly, when peroxide of hydrogen is broken up into water and an oxygen atom is thereby liberated. In commerce the activity of "Sanitas" compounds is due to the formation

of ozone by the slow oxidation of the resin, camphor, and thymol they contain.

Perchloride of Mercury.—Of all the salts of the heavy metals this has been most widely employed, and must be regarded as one of the most powerful and useful of known antiseptics. In testing its action on anthrax spores there is no doubt that in the earlier results its potency was overrated from a neglect of the fact already alluded to, that in the spore-case an albuminate of mercury was formed which prevented the contained protoplasm from developing, while not depriving it of life. It has been found, however, that this salt in a strength of 1–100 will kill the spores in twenty minutes, although an hour's exposure to 1–1000 has no effect. The best results are obtained by the addition to the corrosive sublimate solution of ·5 per cent. of sulphuric acid or hydrochloric acid; the spores will then be killed by a seventy-minute exposure to a 1–200 solution. When, however, organisms in the vegetative condition are being dealt with, much weaker solutions are sufficient; thus anthrax bacilli in blood will be killed in a few minutes by 1–2000, in bouillon by 1–40,000, and in water by 1–500,000. Plague bacilli are killed by one to two minutes' exposure to 1–3000. Generally speaking, it may be said that a 1–2000 solution must be used for the practically instantaneous killing of vegetative organisms.

Perchloride of mercury is one of the substances which has been used for disinfecting rooms by distribution from a spray producer, of which the Equifex may be taken as a type. With such a machine it is calculated that 1 oz. of perchloride of mercury used in a solution of 1–1000 will probably disinfect 3000 square feet of surface. Such a procedure has been extensively used in the disinfection of plague houses, but the use of a stronger solution (1–500 acidulated) is probably preferable.

Formalin as a commercial article is a 40 per cent. solution of formaldehyde in water. This is a substance which of late years has come much into vogue, and it is undoubtedly a valuable antiseptic. A disadvantage, however, to its use is that, when diluted and exposed to air, amongst other changes which it undergoes it may be transformed, under little-understood conditions, into trioxymethylene and paraformaldehyde, these being polymers of formaldehyde. The bactericidal values of these mixtures are indefinite. Formalin may be used either by applying it in its liquid form or as a spray, or the gas which evaporates at ordinary temperatures from the solution may be utilised. To disinfect such an organic mixture as pus containing pyogenic organisms, a 10 per cent. solution acting for half an hour is necessary. In the case of pure cultures, a 5 per cent. solution will kill the cholera organism in three minutes, anthrax bacilli in a quarter of an hour, and the spores in five hours. When such organisms as pyogenic cocci, cholera spirillum, and anthrax bacillus infect clothing, an exposure to the full strength of formalin for two hours is necessary, and in the case of anthrax spores, for twenty-four hours. Silk threads impregnated with the plague bacillus were found to be sterile after two minutes' exposure to formalin.

The action of formalin vapour has been much studied, as its use constitutes a cheap method of treating infected rooms, in which case some spray-producing machine is employed. It is stated that a mixture of 8 c.c. of formalin with 48 c.c. of water is sufficient when vaporised to disinfect one cubic metre, so far as non-sporing organisms are concerned. It is also stated that 1 part formalin in 10,000 of air will kill the cholera

vibrio in one hour, diphtheria bacillus in three hours, the staphylococcus pyogenes in six hours, and anthrax spores in thirteen hours. In the case of organisms which have become dry it is probable, however, that much longer exposures are necessary, but on this point we have no definite information.

Formalin gas has only a limited application; it has little effect on dry organisms, and in the case of wet organisms, in order to be effective, probably must become dissolved so as to give the moisture a proportion analogous to the strengths stated above with regard to the vapour.

Sulphurous Acid.—This substance has long been in use, largely from the cheapness with which it can be produced by burning sulphur in the air. An atmosphere containing ·98 per cent. will kill the pyogenic cocci in two minutes if they are wet, and in twenty minutes if they are dry; and anthrax bacilli are killed by thirty minutes' exposure, but to kill anthrax spores an exposure of from one to two hours to an atmosphere containing 11 per cent. is necessary. For a small room the burning of about a pound and a half (most easily accomplished by moistening the sulphur with methylated spirit) is usually considered sufficient. It has been found that if bacteria are protected, *e.g.*, when they are in the middle of small bundles of clothes, no effect is produced even by an atmosphere containing a large proportion of the sulphurous acid gas. The practical applications of this agent are therefore limited.

Potassium Permanganate.—The action of this agent very much depends on whether it can obtain free access to the bacteria to be killed or whether these are present in a solution containing much organic matter. In the latter case the oxidation of the organic material throws so much of the salt out of action that there may be little left to attack the organisms. Koch found that to kill anthrax spores a 5 per cent. solution required to act for about a day; for most organisms a similar solution acting for shorter periods has been found sufficient, and in the cases of the pyogenic cocci a 1 per cent. solution will kill in ten minutes. There is little doubt that such weaker solutions are of value in disinfecting the throat on account of their non-irritating properties, and good results in this connection have been obtained in cases of diphtheria. A solution of 1 in 10,000 has been found to kill plague bacilli in five minutes.

Carbolic Acid.—Of all the aromatic series this is the most extensively employed antiseptic. All ordinary bacteria in the vegetative condition, and of these the staphylococcus pyogenes is the most resistant, are killed in less than five minutes by a 2–3 per cent. solution in water, so that the 5 per cent. solution usually employed in surgery leaves a margin of safety. But for the killing of such organisms as anthrax spores a very much longer exposure is necessary; thus Koch found it necessary to expose these spores for four days to ensure disinfection. The risk of such spores being present in ordinary surgical procedure may be overlooked, but there might be risk of tetanus spores not being killed, as these will withstand fifteen hours' exposure to a 5 per cent. solution.

In the products of the distillation of coal there occur, besides carbolic acid, many bodies of a similar chemical constitution, and many mixtures of these are in the market—the chief being cyllin, izal, and lysol, all of which are agents of value. Of these lysol is perhaps the most noticeable, as from its nature it acts as a soap, and thus can remove fat and dirt from the hands. A one-third per cent. solution is said to destroy the typhoid and cholera organisms in twenty minutes. A one per cent. solution is sufficient for ordinary surgical procedures.

Iodoform.—This is an agent regarding the efficacy of which there has been much dispute. There is little doubt that it owes its efficiency to its capacity for being broken up by bacterial action in such a way as to set free iodine, which acts as a powerful disinfectant. The substance is therefore of value in the treatment of foul wounds, such as those of the mouth and rectum, where reducing bacteria are abundantly present. It acts more slightly where there are only pyogenic cocci, and it seems to have a specially beneficial effect in tubercular affections. In certain cases its action may apparently be aided by the presence of the products of tissue degeneration.

Aniline Dyes.—Many aniline dyes—methyl-violet, malachite green, brilliant green, etc.—are potent antiseptics. Their action varies considerably on different groups of bacteria, and hence in certain dilutions they can be used in separating the more resistant species, as in certain of the methods already detailed. Recently Browning and his co-workers have called attention to special features possessed by two diaminoacridine compounds, viz. acriflavine (formerly "flavine") and proflavine. They find that not only are they very potent antiseptics but their potency is enhanced by the presence of serum (this property being peculiar to them so far as has been established at present); their inhibitory effect on phagocytosis is relatively small (especially that of acriflavine), and their local and general toxic effects low. The bactericidal action of the two compounds, which is exerted somewhat slowly, is practically the same: they kill staphylococcus aureus in a dilution of 1–100,000 to 1–200,000 in serum. They are generally employed as a solution of 1–1000.

From the results which have been given it will easily be recognised that the choice of an antiseptic and the precise manner in which it is to be employed depend entirely on the conditions under which the bacteria are to be killed. In many cases it will be quite impossible, without original inquiry, to say what course is likely to be attended with most success. In conclusion, it may be said that laboratory experiments alone cannot give accurate information as to the action of antiseptics within the living body, *e.g.*, in a wound.

CHAPTER VI.

RELATIONS OF BACTERIA TO DISEASE—THE PRODUCTION OF TOXINS BY BACTERIA.

Introductory.—It has already been stated that a strict division of micro-organisms into true *parasites* and *saprophytes* cannot be made. No doubt there are organisms, such as the bacillus of tubercle, gonococcus, etc., which are in natural conditions always parasites associated with disease. But these can lead a saprophytic existence in specially prepared conditions, and there are many of the disease-producing organisms, such as the organisms of typhoid and cholera, which can flourish readily outside the body, even in ordinary conditions. A similar statement applies to the terms *pathogenic* and *non-pathogenic.* By the term pathogenic is meant the power which an organism has of producing morbid changes or effects in the animal body, either under natural conditions or in conditions artificially arranged, as in direct experiment. Now we know of no organisms which will in all circumstances produce disease in all animals, and, on the other hand, many bacteria described as harmless saprophytes will produce pathological changes if introduced in sufficient quantity. When, therefore, we speak of a pathogenic organism, the term is merely a relative one, and indicates that in certain circumstances the organism will produce disease, though in the science of human pathology it is often used for convenience as implying that the organism produces disease in man in *natural* conditions.

Modifying Conditions.—In studying the pathogenic effects in any instance, both the micro-organisms and the animal affected must be considered, and not only the species of each, but also its exact condition at the time of infection. In other words, the resulting disease is the product of the sum-total of the characters of the infecting agent, on the one hand, and of the subject of infection, on the other. We may, therefore, state some of the chief circumstances which modify each of these

two factors involved, and, consequently, the diseased condition produced.

1. *The Infecting Agent.*—In the case of a particular species of bacterium its effect will depend chiefly upon (*a*) its virulence, and (*b*) the number introduced into the body. To these may be added (*c*) the path of infection.

The *virulence*, *i.e.*, the power of multiplying in the body and producing disease, varies greatly in different conditions, and the methods by which it can be diminished or increased will be afterwards described (*vide* Chapter XXII.). One important point is that when a bacterium has been enabled to invade and multiply in the tissues of an animal, its virulence for that species is often increased. This is well seen in the case of certain bacteria which are normally present on the skin or mucous surfaces. Thus it has been repeatedly proved that the bacillus coli cultivated from a septic peritonitis is much more virulent than that taken from the bowel of the same animal. The virulence may be still more increased by inoculating from one animal to another in series—the method of *passage*. Widely different effects are, of course, produced on the virulence being altered. For example, a streptococcus which produces merely a local inflammation or suppuration, may produce a rapidly fatal septicæmia when its virulence is raised. Virulence also has a relation to the animal employed, as occasionally on being increased for one species of animal it is diminished for another. For example, streptococci, on being inoculated in series through a number of mice, acquire increased virulence for these animals, but become less virulent for rabbits (Knorr). Certain facts suggest that there may be a periodicity in virulence, *i.e.*, that an organism may for a time produce a relatively mild type of disease and then develop into a more potent strain capable of overcoming the resistance of a greater number of individuals; this would account for the fact that in some diseases widespread epidemics occur at almost fixed intervals of years. The theoretical consideration of virulence must be reserved for a later chapter (see Immunity).

The *number* of the organisms introduced, *i.e.*, the dose of the infecting agent, is another point of importance. The healthy tissues can usually resist a certain number of pathogenic organisms of given virulence, a good example being often furnished in ulcerative endocarditis in man, where bacteria may circulate in the blood for a considerable time without causing secondary lesions. It is only in a few instances that one or two organisms introduced will produce a fatal disease, *e.g.*, the case

of anthrax in white mice. The healthy peritoneum of a rabbit can resist and destroy a considerable number of pyogenic micrococci without any serious result, but if a larger dose be introduced, a fatal peritonitis may follow. There is, therefore, for a particular animal, a minimum lethal dose which can be determined by experiment only; a dose, moreover, which is modified by various circumstances difficult to control.

The path of infection may alter the result, serious effects often following entrance into the blood stream. Staphylococci injected subcutaneously in a rabbit may produce only a local abscess, whilst on intravenous injection multiple abscesses in certain organs may result and death may follow. Local inflammatory reaction with subsequent destruction of the organisms may be restricted to the site of infection or may occur also in the related lymphatic glands. The latter therefore act as a second barrier of defence, or as a filtering mechanism which aids in protecting against blood infection. This is well illustrated in the case of "poisoned wounds." In some other cases, however, the organisms are very rapidly destroyed in the blood stream, and Klemperer has found that, in the dog, subcutaneous injection of the pneumococcus produces death more readily than intravenous injection.

In the case of syphilis, inoculation of monkeys is more successful by scarification than by any other means.

2. *The Subject of Infection.*—Amongst healthy individuals susceptibility to a particular microbe may vary according to (*a*) species, (*b*) race and individual peculiarities, (*c*) age. Different species of the lower animals show the widest variation in this respect, some being extremely susceptible, others highly resistant. Then there are diseases, such as leprosy, syphilis, etc., which under natural conditions are peculiar to the human subject and can only be transmitted to a few of the animals. And further, there are others, such as cholera and typhoid, the typical lesions of which cannot be experimentally reproduced in animals, or appear only imperfectly, although pathogenic effects follow inoculation with the organisms. In the case of the human subject, differences in susceptibility to a certain disease are found amongst different races, and also amongst individuals of the same race, as is well seen in the case of tubercle and other diseases. Age also plays an important part, young subjects being more liable to certain diseases, *e.g.*, to diphtheria. Further, at different periods of life certain parts of the body are more susceptible, for example, in early life, the bones and joints to tubercular and acute suppurative affections.

In increasing the susceptibility of a given individual, conditions of *local or general diminished vitality* play the most important part. It has been experimentally proved that conditions such as exposure to cold, fatigue, starvation, etc., all diminish the natural resistance to bacterial infection. Rats naturally immune to glanders can be rendered susceptible by being fed with phloridzin, which produces a sort of diabetes, a large amount of sugar being excreted in the urine (Leo). Also a local susceptibility may be produced by injuring or diminishing the vitality of a part. If, for example, previous to an intravenous injection of staphylococci, the aortic cusps of a rabbit be injured, the organisms may settle there and set up an ulcerative endocarditis; or if a bone be injured, they may produce suppuration at the part, whereas in ordinary circumstances these lesions would not take place.

Such facts, established by experiment (and many others might be given), illustrate the important part which local or general conditions of diminished vitality may play in the production of disease in the human subject. This has long been known by clinical observation. In normal conditions the blood and tissues of the body, with the exception of the skin and certain of the mucous surfaces, are bacterium-free, and if a few organisms gain entrance, they are destroyed. But if the vitality becomes lowered, their entrance becomes easier and the possibility of their multiplying and producing disease greatly increased. In this way the favouring part played by fatigue, cold, etc., in the production of diseases, of which the direct cause is a bacterium, may be understood. It is important to keep in view in this connection that many of the inflammation-producing and pyogenic organisms are normally present on the skin and various mucous surfaces; and also that during epidemics of a disease, *e.g.*, typhoid, cholera, meningitis, diphtheria, the pathogenic organisms may be present on the mucous membranes of healthy individuals—that is, may have gained access to the body without producing the disease. The action of a certain organism may devitalise the tissues to such an extent as to pave the way for the entrance of other bacteria; we may mention the liability of the occurrence of pneumonia, erysipelas, and various suppurative conditions, in the course of or following infective fevers. In some cases the specific organism may produce lesions through which the other organisms gain entrance, *e.g.*, in typhoid, diphtheria, etc. A notable example of diminished resistance to bacterial infection is seen in the case of diabetes; tuberculosis and infection with pyogenic organisms are prone to occur in this

disease, and are apt to be of a severe character. It is not uncommon to find in the bodies of those who have died from chronic wasting disease, collections of micrococci or bacilli in the capillaries of various organs, which have entered in the later hours of life—that is to say, the bacterium-free condition of the blood has been lost in the period of prostration preceding death.

The methods by which the natural resistance may be specifically increased belong to the subject of immunity, and are described in the chapter on that subject.

Carriers.—As has been stated, many of the organisms which produce inflammatory and suppurative affections are normally present on the skin or mucous membranes; but it has also been established that several of the causal agents of acute infectious diseases, such as typhoid, epidemic meningitis, diphtheria, etc., may flourish on the mucous membranes of individuals in apparent health. Such individuals are known as "carriers," and they play a highly important part in the spread of these infections. It will be shown more fully below that many of the pathogenic bacteria, as regards their morphological and cultural characters, are very similar to, and have apparently sprung from, organisms which are normally present in the sites of the several lesions. Thus the whole typhoid-dysentery group are related to the b. coli, and the meningococci to various Gram-negative diplococci which abound in the naso-pharynx. The carrier state may thus be regarded, in a sense, as a return of these organisms to a saprophytic existence. One group of carriers is constituted by those who have suffered from the disease, and in whom the organism persists after recovery, and these are usually designated "temporary" or "chronic" according to the duration of the condition. The proportion of those who become carriers, and the period of carrying the organisms, vary in different diseases. In cholera, for example, the period is usually comparatively short, whereas in typhoid the organisms not infrequently persist for an indefinite period of time. The other group of carriers comprises apparently healthy individuals, who harbour the organisms and are not known to have suffered from the disease. Some of these may really have had a mild attack, but in others there is no evidence of this; a few subsequently develop the disease,—"precocious" carriers. In many instances previous contact with a case of the disease can be traced; this is a usual occurrence with typhoid carriers. On the other hand, no connection of this kind may be discoverable; for instance, the meningococcus is often found, especially during epidemics, in "non-contacts," the

organism apparently spreading widely from individual to individual in the community. Further facts will be given in connection with the special diseases.

Modes of Bacterial Action.—In the production of disease by micro-organisms there are two main factors involved, namely, (*a*) the multiplication of the living organisms after they have entered the body, and (*b*) the production by them of poisons which may act both upon the tissues around and upon the body generally. The former corresponds to *infection*, the latter is of the nature of *intoxication* or poisoning. In different diseases one of these is usually the more prominent feature, but both are always more or less concerned.

1. *Infection and Distribution of the Bacteria in the Body.*—After pathogenic bacteria have invaded the tissues, or in other words, after infection by bacteria has taken place, their further behaviour varies greatly in different cases. In certain cases they may reach and multiply in the blood stream, producing a fatal septicæmia. In the lower animals this multiplication of the organisms in the blood throughout the body may be very extensive (for example, the septicæmia produced by the pneumococcus in rabbits); but in septicæmia in man it is seen in less degree, the organisms rarely remain in large numbers in the circulating blood, and their detection in it during life by microscopic examination is rare, and even culture methods may give negative results unless a large amount of blood is used. In such cases, however, the organisms may be found *post mortem* lying in large numbers within the capillaries of various organs, *e.g.*, in cases of septicæmia produced by streptococci. In the human subject more frequently one of two things happens. In the first place, the organisms may remain local, producing little reaction around them, as in tetanus, or a well-marked lesion, as in diphtheria, etc. Or in the second place, they may pass by the lymph or blood stream to other parts or organs in which they settle, multiply, and produce lesions, as in tubercle.

2. *Production of Chemical Poisons.*—In all these cases the growth of the organisms is accompanied by the formation of *chemical products*, which act generally or locally in varying degree as toxic substances. The toxic substances become diffused throughout the system, and their effects are manifested chiefly by symptoms such as the occurrence of fever, disturbances of the circulatory, respiratory, and nervous systems, etc. In some cases corresponding changes in the tissues are found, for example, the changes in the nervous system in diphtheria, to be

afterwards described. The general toxic effects may be so slight as to be of no importance, as in the case of a local suppuration; or they may be very intense, as in pyæmia; or, again, less severe but producing cachexia by their long continuance, as in tuberculosis.

The occurrence of *local tissue changes or lesions* produced in the neighbourhood of the bacteria, as already mentioned, is one of the most striking results of bacterial action, but these also must be traced to chemical substances formed in or around the bacteria, and either directly or through the medium of ferments. In this case it is more difficult to demonstrate the mode of action, for in the tissues the chemical products are formed by the bacteria slowly, continuously, and in a certain degree of concentration, and these conditions cannot be exactly reproduced by experiment. It is also to be noted that more than one poison may be produced by a given bacterium, *e.g.*, the tetanus bacillus (p. 429). Further, it is very doubtful whether all the chemical substances formed by a certain bacillus growing in the tissues are also formed by it in cultures outside the body (*vide* p. 188). The separated toxin of diphtheria, like various vegetable and animal toxins, however, possesses a local toxic action of very intense character, evidenced often by extensive necrotic change.

The injection of large quantities of many different pathogenic organisms in the *dead* condition results in the production of a local inflammatory change which may be followed by suppuration, this effect being possibly brought about by certain substances in the bacterial protoplasm common to various species, or at least possessing a common physiological action (Buchner and others). When dead tubercle bacilli, however, are introduced into the blood stream, nodules do result in certain parts which have a resemblance to ordinary tubercles. In this case the bodies of the bacilli evidently contain a highly resistant and slowly acting substance which gradually diffuses around and produces effects (*vide* Tuberculosis).

Summary.—We may say, then, that the action of bacteria as disease-producers, as in fact their power to exist and multiply in the living body, depends upon the chemical products formed directly or indirectly by them. This action is shown by *tissue changes* produced in the vicinity of the bacteria or throughout the system, and by *toxic symptoms* of great variety of degree and character.

We shall first consider the effects of bacteria on the body generally, and afterwards the nature of the chemical products.

Effects of Bacterial Action.

These may be for convenience arranged in a tabular form as follows :—

A. Tissue Changes.

(1) Local changes, *i.e.*, changes produced in the neighbourhood of the bacteria.

Position : (*a*) At primary lesion.
(*b*) At secondary foci.

Character : (*a*) Tissue reactions } Acute or
(*b*) Degeneration and necrosis } chronic.

(2) Produced at a distance from the bacteria, directly or indirectly, by the absorption of toxins.

(*a*) In special tissues—
(*α*) as the result of damage, *e.g.*, nerve cells and fibres, secreting cells, vessel walls, or
(*β*) changes of a reactive nature in the blood-forming tissues and organs.

(*b*) General anatomical changes, the effects of malnutrition or of increased waste.

B. Symptoms and Changes in Metabolism.

The occurrence of fever, of errors of assimilation and elimination, etc.

A. Tissue Changes produced by Bacteria.—The effects of bacterial action are so various as to include almost all known pathological changes. However varied in character, they may be classified under two main headings : (*a*) those of a degenerative or necrotic nature, the direct result of damage ; and (*b*) those of reactive nature, defensive or reparative. The former are the expression of the necessary vulnerability of the tissues, the latter of protective powers evolved for the benefit of the organism. In the means of defence both leucocytes and the fixed cells of the tissues are concerned. Both show phagocytic properties, *i.e.*, have the power of taking up bacteria into their protoplasm. The cells are guided towards the focus of infection by chemiotaxis, and thus we find that different bacteria attract different cells. The most rapid and abundant supply of phagocytes is seen in the case of suppurative conditions where the neutrophile leucocytes of the blood are chiefly concerned. When the local lesion is of some extent there is usually an increase of these cells

in the blood—a neutrophile leucocytosis. And further, observation has shown that associated with this there is in the bone-marrow an increased number of the mother-cells of these leucocytes—the neutrophile myelocytes. The passage of the neutrophile leucocytes from the marrow into the blood, with the resulting leucocytosis, is also apparently due to the absorbed bacterial toxins acting chemiotactically on the marrow. These facts abundantly show that the means of defence is not a mere local mechanism, but that increased proliferative activity in distant tissues is called into play. In addition to direct phagocytosis by these leucocytes, there is now abundant evidence that an important function is the production in the body of bactericidal and other antagonistic substances. In other cases the cells chiefly involved are the mononuclear hyaline leucocytes, and with them the endothelial cells, *e.g.*, of serous membranes, often play an important part in the defence; this is well seen in typhoid fever, where the specific bacillus appears to have little or no action on the neutrophile leucocytes. In other cases, again, the reaction is chiefly on the part of the connective cells, though their proliferation is always associated with some variety of leucocytic infiltration and usually also with the formation of new blood vessels. Such a connective tissue reaction occurs especially in slow infections or in the later stages of an acute infection. The reactive tissue changes in the presence of bacterial invasion are naturally very varied,—examples of this will be found in subsequent chapters,—but they may be said to be manifestations of the two fundamental processes of (*a*) increased functional activity—movement, phagocytosis, secretion, etc.—and (*b*) increased formative activity—cell growth and division. The exudation from the blood vessels has been variously interpreted. There is no doubt that the exudate may have bactericidal or opsonic properties and also acts as a diluting agent, but it must still be held as uncertain whether the process of exudation ought to be regarded as primarily defensive or as the direct result of damage to the endothelium of the vessels. It may also be pointed out that the various changes referred to are none of them peculiar to bacterial invasion; they are examples of the general laws of tissue change under abnormal conditions, and they can all be reproduced by chemical substances in solution or in a particulate state. What constitutes their special feature is their progressive or spreading nature, due to the bacterial multiplication.

(1) *Local Lesions.*—In some diseases the lesion has a special site; for example, the lesion of typhoid fever, and, to a less

extent, that of diphtheria. In other cases it depends entirely upon the point of entrance, *e.g.*, malignant pustule and the conditions known as wound infections. In others again, there is a special tendency for certain parts to be affected, as the upper parts of the lungs in tubercle. In some cases the site has a mechanical explanation.

When organisms gain an entrance to the blood from a primary lesion, the organs specially liable to be affected vary greatly in different diseases. Pyogenic cocci show a special tendency to settle in the capillaries of the kidneys and produce miliary abscesses, whilst these lesions rarely occur in the spleen. On the other hand, the nodules in disseminated tubercle or glanders are much more numerous in the spleen than in the kidneys, which in the latter disease are usually free from them. The distribution of the lesions thus cannot be explained on a mechanical basis. Even in the case of the lesions produced by dead tubercle bacilli, a certain selective character is observed.

Acute Local Lesions.—The local inflammatory reaction presents different characters in different conditions. It may be accompanied by abundant fibrinous exudation, or by great catarrh (in the case of an epithelial surface), or by hæmorrhage, or by œdema; it may be localised or spreading in character; it may be followed by suppuration, and may lead up to necrosis of the tissues of the part, a good example of the latter event being found in a boil. Examples will be given in subsequent chapters. The necrotic or degenerative changes affecting especially the more highly developed elements of tissues are chiefly produced by the direct action of the bacterial poisons, though aided by the disturbances of nutrition involved in the vascular phenomena. It may here be pointed out that a well-marked inflammatory reaction is often found in animals which occupy a medium position in the scale of susceptibility, and that an organism which causes a general infection in a certain animal may produce only a local inflammation when its virulence is lessened.

Chronic Local Lesions.—In a considerable number of diseases produced by bacteria the local tissue reaction is a more chronic process than those described; there is less vascular disturbance and a greater preponderance of the proliferative processes, leading to new formation of connective tissue. This formation may occur in foci here and there, so that nodules result, or it may be more diffuse. Such changes especially occur in the diseases often known as the *infective granulomata*, of which tubercle, leprosy, glanders, actinomycosis, syphilis, etc., are examples.

(2) *General Lesions produced by Toxins.*—In the various infective conditions produced by bacteria, changes commonly occur in certain organs unassociated with the presence of the bacteria; these are produced by the action of bacterial products circulating in the blood. Many such lesions can be produced experimentally. The secreting cells of various organs, especially the kidney and liver, are specially liable to change of this kind. Cloudy swelling, which may be followed by fatty change or by actual necrosis with granular disintegration, is common. Hyaline change in the walls of arterioles may occur, and in certain chronic conditions amyloid change is brought about in a similar manner. The latter has been produced in animals by repeated injections of the staphylococcus aureus. Capillary hæmorrhages are not uncommon, and are in many cases due to an increased permeability of the vessel walls, aided by changes in the blood plasma, as evidenced sometimes by diminished coagulability. Similar hæmorrhages may follow the injection of some bacterial toxins, *e.g.*, of diphtheria, and also of vegetable poisons, *e.g.*, ricin and abrin. Skin eruptions occurring in the exanthemata are probably produced in the same way, though in many of these diseases the causal organism has not yet been isolated. We have, however, the important fact that corresponding skin eruptions may be produced by poisoning with certain drugs. In the nervous system degenerative changes have been found in diphtheria, both in the spinal cord and in the peripheral nerves, and have been reproduced experimentally by the products of the diphtheria bacilli. It is probable that some of the lesions of the nervous system occurring in syphilis have likewise a toxic origin. Besides the effects on tissues enumerated, more subtle changes, *e.g.*, those observed in the reaction and coagulability of the blood, are also probably traceable to toxic effects.

B. Disturbances of Metabolism, etc.—It will easily be realised that such profound tissue changes as have been detailed cannot occur without great interference with the normal bodily metabolism. General malnutrition and cachexia are of common occurrence, and it is a striking fact found by experiment that after injection of bacterial products, *e.g.*, of the diphtheria bacillus, a marked loss of body weight often occurs which may be progressive, leading to the death of the animal. In bacterial disease assimilation is often imperfect, for the digestive glands are affected, it may be, by actual poisoning by bacterial products, it may be by the occurrence of fever, and excretion is interfered with by the damage done to the excretory cells. But of all the changes

in metabolism the most difficult to understand is the occurrence of that interference with the heat-regulating mechanism which results in fever. The degree and course of the latter vary, sometimes conforming to a more or less definite type, where the bacilli are selective in their field of operation, as in croupous pneumonia or typhoid, sometimes being of a very irregular kind, especially when the bacteria from time to time invade fresh areas of the body, as in pyæmic affections. The main point of interest regarding the development of fever is as to whether it is a direct effect of the circulation of bacterial toxins, or if it is to be looked on as part of the reaction of the body against the irritant. This question has still to be settled, and all that we can do is to adduce certain facts bearing on it. Thus in diphtheria and tetanus, where toxic action leading to degeneration plays such an important part, fever may be a very subsidiary feature, except in the terminal stage of the latter disease; and in fact in diphtheria profoundly toxic effects may be produced with little or no interference with heat regulation. On the other hand, in bacterial disease, where defensive and reparative processes predominate, fever is rarely absent, and it is nearly always present when there is an active leucocytosis going on. In this connection it may be remarked that several observers have found that, when a relatively small amount of the dead bodies of certain bacteria are injected into an animal, fever occurs; while the injection of a large amount of the same is followed by subnormal temperatures and rapidly fatal collapse. It might appear as if this indicated that the occurrence of fever had a beneficial effect, but this is one of the points at issue. Certainly such an effect is not due to the bacteria being unable to multiply at the higher degrees of temperature occurring in fever, for this has been shown not to be the case. Whether the increase of bodily temperature indicates the occurrence of changes resulting in the production of bactericidal bodies, etc., is very doubtful; a production of antagonistic substances may be effected without the occurrence of fever or of any apparent disturbance of health.

Symptoms.—Many of the symptoms occurring in bacterial infections are produced by the histological changes mentioned, as can be readily understood; whilst in the case of others, corresponding changes have not yet been discovered. Of the latter, those associated with fever, with its disturbances of metabolism and manifold affections of the various systems, are the most important. The nervous system is especially liable to be affected—convulsions, spasms, coma, paralysis etc., being

common. The symptoms due to disturbance or abolition of the functions of secretory glands also constitute an important group, forming, as they do, a striking analogy to what is found in the action of various drugs.

These tissue changes and symptoms are given only as illustrative examples, and the list might easily be greatly amplified. The important fact, however, is that *nearly all, if not quite all, the changes found throughout the organs (without the actual presence of bacteria), and also the symptoms occurring in infective diseases, can either be experimentally reproduced by the injection of bacterial poisons or have an analogy in the action of drugs.*

The Toxins produced by Bacteria.

Early Work on Toxins.—The first to study systematically the production of bacterial toxins was Brieger, who isolated from putrefying substances, and also from bacterial cultures, nitrogen-containing bodies, which he called *ptomaines.* Similar bodies occurring in the ordinary metabolic processes of the body had previously been described and called *leucomaines.* Ptomaines isolated from pathogenic bacteria in no case reproduced the symptoms of the disease. The methods by which they were isolated were faulty, and they have therefore only a historic interest. The introduction of the principle of rendering fluid cultures bacteria-free by filtration through unglazed porcelain, and its application by Roux and Yersin to obtain, in the case of the b. diphtheriæ, a solution containing a toxin which reproduced the symptoms of this disease (*vide* Chapter XVI.), constitute the starting-point of modern work on the subject.

General Facts regarding Bacterial Toxins.—In dealing with the action of toxins it is necessary to distinguish between the effects produced by the actual constituents of the bacterial protoplasm (intrabacterial toxins, endotoxins) and those which in a few bacteria are traceable to soluble substances passing out into the media in which these bacteria may be growing (extra-bacterial toxins, exotoxins). The former are concerned in the action of by far the greater number of pathogenic bacteria; the latter account for the pathogenic processes originated in a limited number of cases of which diphtheria and tetanus are the most important. This distinction is important as, in consequence of these last two diseases having had much attention directed towards them early in the history of research on the subject, there has hitherto been too much tendency to take for granted that poisons of a similar constitution are concerned in all cases

of bacterial intoxication. At present such an assumption is not justified by facts, and we do not even know whether the endotoxins and exotoxins belong to the same group of chemical bodies. The terms are merely used as a convenient means of accentuating a difference in solubility between the two groups of toxic bodies.

Endotoxins.—The dead bodies of certain bacteria have been found to be very toxic. When, for instance, tubercle bacilli are killed by heat and injected into the body tissues of a susceptible animal, tubercular nodules are found to develop round the sites where they have lodged. From this it is inferred that they must have contained characteristic toxins, seeing that characteristic lesions result. The bodies of such organisms as the pyogenic cocci, the b. typhosus, and the v. choleræ likewise give rise to pathogenic effects. Such toxins may appear in the fluids in which the bacteria are living (1) by excretion in an unaltered or altered condition, (2) by the disintegration of the bodies of the organisms which we know are always dying in any bacterial growth. The death of bacteria occurs also in the body of an infected animal, and the disintegration of these dead bacteria constitutes an important means by which the poisons they contain are absorbed. There is some evidence that during growth bacteria often originate poisons which are hurtful to their own vitality, and also that ferments are produced by them which have a solvent effect on the poisoned members of the colony. Such a process of *autolysis*, as it has been called, may have an important result in liberating endotoxins. It is impossible, at present, to obtain these toxins apart from other derivatives of the bacterial protoplasm. Our knowledge concerning their action is chiefly derived from the study of the effects produced by injecting into animals either the bodies of bacteria (killed by chloroform vapour or by heat) or bacterial protoplasm disintegrated mechanically or artificially autolysed. When effects are produced by such injections they do not present in any particular case specific characters. They usually appear very soon, it may be in a few hours after injection of the toxic material; there is not the definite period of incubation which with other toxins often elapses before symptoms appear.

Aggressins.—In certain cases there is difficulty in understanding the action of bacteria which neither form soluble toxins in a fluid medium nor possess a highly toxic protoplasm, and which yet produce effects at a distance from the focus of infection, *e.g.*, b. anthracis. To explain such occurrences it has long been regarded as a possibility that some bacteria are

only capable of producing toxins within the animal tissues, and it has further been thought possible that bacteria, such as, for example, the typhoid bacillus, which do distribute into media intracellular toxins, might either produce these toxins more readily in the tissues or might produce in addition other toxins of a different nature. During recent years such toxins have been much studied, and the name *aggressins* has been given to them. The evidence adduced for the existence of these aggressins as a separate group of bacterial poisons is of the following kind: An animal is killed by a dose of the typhoid, dysentery, cholera, or tubercle bacillus, or by a staphylococcus, the organism being introduced into one of the serous cavities. After death the serous exudate, which in all these cases is present, is taken, and centrifuged to remove the bacteria so far as this can be done by such a procedure; the bacteria which are left are killed by shaking the fluid up with toluol and leaving it to stand for some days. Such a fluid in a dose which by itself has no pathogenic effect, has the property of transforming a non-lethal dose of the bacterium used into one having fatal effect. Further, the effects of the combined actions of the bacteria and aggressins are often of a much more acute character than can be obtained with toxic products developed *in vitro*. The effects produced by aggressins are attributed to a paralysing action on the phagocytic functions of the leucocytes. The subject is full of difficulties, and in the case of certain of the organisms employed results similar to those attributed to aggressin action have been observed with the fluid obtained by macerating living cultures,—the deduction being that in the aggressins we are merely dealing with a particular type of endotoxin. As evidence of the existence of a special group of toxins, it has been stated that a special type of immunity against the aggressins can be originated. Perhaps the most important aspect of the controversy is the recognition of the existence of toxins having an action on the leucocytes. A poison causing death of these cells in connection with the pus-forming action of the pyogenic cocci has been described under the name of leucocidin, and Eisenberg records that in *in vitro* mixtures of leucocytes and cultures of the bacillus of symptomatic anthrax loss of motility and degeneration of the cells may be observed.

The non-specific effects of toxins are responsible for the general changes occurring in the greater number of the common bacterial infections in man.

Exotoxins.—In the cases of a few pathogenic bacteria the media in which they are growing become extremely toxic. This

is more marked in some cases than in others. The two best examples of bacteria thus producing soluble toxins are the diphtheria and tetanus bacilli. In these and similar cases when bouillon cultures are filtered bacterium-free by means of a porcelain filter, toxic fluids are obtained, which on injection into animals reproduce the highly characteristic symptoms of the corresponding diseases. This contrasts with such cases as those of the pneumococcus or of b. anthracis, filtered cultures of which are usually non-toxic. Poisons appearing in culture media have been called extracellular toxins or *exotoxins*, but we cannot as yet say whether they are excreted by the bacteria or whether they are produced by the bacteria acting on the constituents of the media. The exotoxins are easily obtainable in large quantities, but no method has been discovered of obtaining them in a pure form, and our knowledge of their properties is exclusively derived from the study of the toxic filtrates of bouillon cultures—these filtrates being usually referred to simply as the toxins. These toxins differ in their effects from the endotoxins in that specific actions on certain tissues are often manifested. Thus the toxins of the diphtheria, the tetanus, and the botulismus bacilli all act on the nervous system; with some of the pyogenic bacteria, on the other hand, poisons, probably of similar nature, produce solution of red blood corpuscles (this last might be thought to explain the anæmias so common in the associated diseases, but here further work is still necessary). In the action of many of these toxins the occurrence of a period of incubation between the introduction of the poison into the animal tissues and the appearance of symptoms is often a feature.

Amongst the properties of the exotoxins are the following: They are apparently all uncrystallisable; they are soluble in water and they are dialysable; they are precipitated along with proteids by concentrated alcohol, and also by ammonium sulphate; if they are proteids they are either albumoses or allied to the albumoses; they are often relatively unstable, having their toxicity diminished or destroyed by heat (the degree of heat which is destructive varies much in different cases), light, and by certain chemical agents. Their potency is often altered in the precipitations practised to obtain them in a pure or concentrated condition, but among the precipitants ammonium sulphate has little if any harmful effect. Regarding the endotoxins we know much less, but it is probable that, chemically, their nature is similar, though some of them at least are not so easily injured by heat, *e.g.*, those of the tubercle

bacillus, already mentioned. In the case of all toxins the fatal dose for an animal varies with the species, body weight, age, and previous conditions as to food, temperature, etc. In estimating the minimal lethal dose of a toxin these factors must be carefully considered.

The following is the best method of obtaining concentrated exotoxins: The toxic fluid is placed in a shallow dish, and ammonium sulphate crystals are well stirred in till no more dissolve. Fresh crystals to form a bulk nearly equal to that of the whole fluid are added, and the dish is set in an incubator at 37° C. overnight. Next day a brown scum of precipitate will be found floating on the surface. This contains the toxin. It is skimmed off with a spoon, placed in watch-glasses; these are dried *in vacuo* and stored in the dark, also *in vacuo*, or in an exsiccator containing strong sulphuric acid. For use the contents of one are dissolved up in a little normal saline solution.

The whole question of the parts played by toxins in bacterial action is manifestly very complex. On the one hand, we have a few processes, for example, diphtheria and tetanus, in which very characteristic effects are produced on special tissues, by soluble toxins. On the other hand, we have the great mass of bacterial infections, in which the toxic effects are of a non-specific character, in the sense that they are not the result of an action on any particular tissue in the body, but on the vital processes of the organism as a whole. There is thus the possibility that with any one species of organism different effects may be produced by, it may be, different elements in the protoplasm of the invading bacterial cell. Some of these elements may act on such specialised body cells as those of the nervous system, liver, or kidneys, giving rise to disturbances of metabolism. Other poisonous elements may mainly act on the defensive cells of the body, *e.g.*, the leucocytes. A small dose of toxin may stimulate these cells to an activity which results in the infection being thrown off, either by the poison being neutralised, or by the supply of toxin being cut off by the killing of the bacterium producing it. A large dose of such a toxin, may, on the other hand, altogether break down the defensive mechanism of the invaded body. Even in such an apparently simple case as diphtheria there is a complexity as the bacteria give rise to a local inflammation and to a general toxæmia initiated by the specific toxin.

There is another point which must be kept in view, namely, that some of the phenomena which have been regarded as dependent upon the activity of bacterial toxins may possibly be related to the little-understood process of anaphylaxis (see

Immunity). Anaphylaxis essentially consists in the development under certain circumstances in an animal of a hypersensitiveness to foreign albuminous materials which in themselves are not toxic. Effects of the gravest kind may be produced during this period of hypersensitiveness, and it has been thought that some of the phenomena of an infectious disease, *e.g.*, the intervention of an incubation period before symptoms occur, may be accounted for by the gradual development of hypersensitiveness to the proteins of the invading bacteria. It may be said here that the effect seen when horse serum is injected into a rabbit during its hypersensitive stage to this substance bears a striking resemblance to what is seen in natural infection in man by the cholera vibrio.

The phenomena of any bacterial disease may thus in reality be due to very different and complex causes.

The Nature of Toxins.—There is comparatively little known regarding this subject. The fact that many exotoxins are precipitated along with albumoses suggested the idea that they are formed from the medium in which the bacteria are growing by processes analogous to those of gastric digestion. Sidney Martin found that albumoses [1] and peptones were formed by the action of certain pathogenic bacteria, and that the precipitate containing these albumoses was toxic. A similar digestive action has been traced in the case of the tubercle bacillus by Kühne.

Further evidence that bacterial toxins are either albumoses or bodies having a still smaller molecule was adduced by C. J. Martin. This worker, by filling the pores of a Chamberland bougie with gelatin, obtained what is practically a strongly supported colloid membrane through which dialysis can be made to take place under great pressure, say, of compressed oxygen.

[1] In the digestion of albumins by the gastric and pancreatic juices, the albumoses are a group of bodies formed preliminarily to the production of peptone. Like the latter they differ from the albumins in their not being coagulated by heat, and in being slightly dialysable. They differ from the peptones in being precipitated by dilute acetic acid in presence of much sodium chloride, and also by neutral saturated sulphate of ammonia. Both are precipitated by alcohol. The first albumoses formed in digestion are proto-albumose and hetero-albumose, which differ in the insolubility of the latter in hot and cold water (insolubility and coagulability are quite different properties). They have been called the primary albumoses. By further digestion both pass into the secondary albumose, deutero-albumose, which differs slightly in chemical reactions from the parent bodies, *e.g.*, it cannot be precipitated from watery solutions by saturated sodium chloride unless a trace of acetic acid be present. Dysalbumose is probably merely a temporary modification of hetero-albumose. Further digestion of deutero-albumose results in the formation of peptone.

He found that in such an apparatus toxins—at least two kinds tried—will pass through just as an albumose will.

On the other hand, certain facts indicate that the exotoxins like the endotoxins are the product of internal metabolism in bacteria. Thus Brieger and Boer, working with bouillon cultures of diphtheria and tetanus, separated, by precipitation with zinc chloride, bodies which show characteristic toxic properties, but which had the reactions neither of peptone, albumose, nor albuminate, and the nature of which is unknown. It has also been found that the bacteria of tubercle, tetanus, diphtheria, and cholera can produce toxins when growing in proteid-free fluids. Further investigation is here required, for Uschinsky, applying Brieger and Boer's method to a toxin so produced, states that the toxic body is not precipitated by zinc salts, but remains free in the medium. If the toxins are really non-proteid they may, on the one hand, be the final product of a digestive action—extra- or intracellular—or they may be the manifestation of a separate vital activity on the part of the bacteria. On the latter theory the toxicity of the toxic albumoses of Sidney Martin may be due to the precipitation of the true toxins along with these other bodies. From the chemical standpoint this is quite possible. Of the nature of the endotoxins nothing is known.

When we take into account the extraordinary potency of these poisons (in the case of tetanus the fatal dose of the pure poison for a guinea-pig must often be less than ·000001 grm.), we can understand how, altogether apart from their instability, attempts by present chemical methods to isolate them in a pure condition are not likely to be successful, and of their real nature we know nothing. Friedberger and Moreschi have shown that the intravenous injection in the human subject of a fraction of a loopful of a dead typhoid culture gives rise to toxic symptoms, including marked febrile reaction. Such injections are followed by the appearance of agglutinating and bacteriolytic substances in the serum. These results show that intracellular toxins may be comparable with extracellular toxins so far as concerns the extremely small dose sufficient to produce toxic effects.

The comparison of the action of bacteria in the tissues in the production of these toxins to what takes place in the gastric digestion, has raised the question of the possibility of the elaboration by these bacteria of *ferments* by which the process may be started. Thus Sidney Martin put forward the view that ferments may be produced which we may look on as the primary toxic agents, and which act by digesting surrounding material and producing albumoses — these bodies being, as it were, secondary poisons. Hitherto all attempts at the isolation of bacterial ferments of such a nature have failed.

But apart from the fact that with such bacteria as those of tetanus and diphtheria, toxins may have a digestive origin, analogies have been drawn between ferment and toxic action. The chief facts upon which these have been founded are as follows: Thus the toxic products of these and other bacteria lose their toxicity by exposure to a temperature which puts an end to the activity of such an undoubted ferment as that of the gastric juice. If diphtheria toxin be heated at 65° C. for one hour, it loses much of its toxic effect, and in the case of b. tetani all the toxicity is lost by exposure at this temperature. In regard to both diseases there is a still further fact which is adduced in favour of the toxic substances being of the nature of ferments, namely, the existence of a definite period of incubation between the injection of the toxic bodies and the appearance of symptoms. This may be interpreted as showing that after the introduction of, say, a filtered bouillon culture, further chemical substances are formed in the body before the actual toxic effect is produced. Too much reliance must not be placed on such an argument, for in the case of tetanus, at least, the delay may be explained by the fact that the poison apparently has to travel up the nerve trunks before the real poisonous action is developed. Further, with some poisons presently to be mentioned which are closely allied to the bacterial toxins, an incubation period may not exist. It would not be prudent to dogmatise as to whether the toxins do or do not belong to such an ill-defined group of substances as the ferments. It may be pointed out, however, that the essential concept of a ferment is that of a body which can originate change without itself being changed, and no evidence has been adduced that toxins fulfil this condition. Another property of ferments is that so long as the products of fermentation are removed, the action of a given amount of ferment is indefinite. Again, in the case of toxins no evidence of such an occurrence has been found. A certain amount of a toxin is always associated with a given amount of disease effect, though a process of elimination of waste products must be all the time going on in the animal's body. Again, too much importance must not be attached to loss of toxicity by toxins at relatively low temperatures. This is not true of all toxins, and furthermore many proteids show a tendency to change at such temperatures; for instance, if egg albumin be kept long enough at 55° C. nearly the whole of it will be coagulated. We must therefore maintain an open mind on this subject.

Similar Vegetable and Animal Poisons.—It has been found that the bacterial poisons belong to a group of toxic bodies all presenting very similar properties, other members of which occur widely in the vegetable and animal kingdoms. Among plants the best-known examples are the ricin and abrin poisons obtained by making watery emulsions of the seeds of the *Ricinus communis* and the *Abrus precatorius* (jequirity) respectively. From the *Robinia pseudacacia* another poison—robin—belonging to the same group is obtained. The chemical reactions of ricin and abrin correspond to those of the bacterial toxins. They are soluble in water, they are precipitable by alcohol, but being less easily dialysable than the albumoses they have been called toxalbumins. Their toxicity is seriously impaired by boiling, and they also gradually become less toxic on being kept. Both are among the most active poisons known—ricin being the more powerful. When they are injected subcutaneously a period of twenty-four hours usually elapses —whatever be the dose—before symptoms set in. Both tend to produce

great inflammation at the seat of inoculation, which in the case of ricin may end in an acute necrosis ; in fatal cases hæmorrhagic enteritis and nephritis may be found. Both act as irritants to mucous membranes, abrin especially being capable of setting up most acute conjunctivitis. In the action of a poisonous fungus, *Amanita phalloides*, a similar toxin is at work. After an incubation period of some hours, symptoms of abdominal pain, diarrhœa with bloody stools, and, later, jaundice occur. *In vitro* the toxin has a hæmolytic action. Like other poisons of this class, an antitoxin can be produced towards the fungus poison.

It is also certain that the poisons of bees, of scorpions, and of poisonous snakes belong to the same group. The poisons derived from the last are usually called venins, and a very representative group of such venins derived from different species has been studied. To speak generally, there is derivable from the natural secretions of the poison glands a series of venins which have all the reactions of the bodies previously considered. Like ricin and abrin, they are not so easily dialysable as bacterial toxins, and therefore have also been classed as toxalbumins. Their properties are also similar ; many of them are destroyed by heat, but the degree necessary here also varies much, and some will stand boiling. There is also evidence that in a crude venin there may be several poisons differently sensitive to heat. All the venins are very powerful poisons, but here there is practically no period of incubation—the effects are almost immediate. An outstanding feature of the venins is the complexity of the crude poison secreted by any particular species of snake. C. J. Martin, in summing up the results of many observers, has pointed out that different venoms have been found to contain one or more of the following poisons : a neurotoxin acting on the respiratory centre ; a neurotoxin acting on the nerve-endings in muscle ; a toxin causing hæmolysis ; toxins acting on other cells, *e.g.*, the endothelium of blood vessels (this from its effects has been named hæmorrhagin), leucocytes, nerve-cells ; a toxin causing thrombosis ; a toxin having an opposite effect and preventing coagulation ; a toxin neutralising the bactericidal qualities of the body fluids and thus favouring putrefaction ; a toxin causing agglutination of the red blood corpuscles ; a proteolytic ferment ; a toxin causing systolic standstill of the excised heart. Any particular venom contains a mixture in varying proportions of such toxins, and the different effects produced by the bites of different snakes largely depend on this variability of composition. The neurotoxic, the thrombotic, and the hæmolytic toxins are very important constituents of any venom. The toxicity of different venoms varies much, and no general statement can be made with regard to the toxicity of different poisons towards man. Lamb calculated that the fatal dose of crude cobra venom for man is probably about ·015 of a gramme, and that if such a snake bites with full glands many times this dose would probably be injected, but, of course, the amount emitted depends largely on the period which has elapsed since the animal last emptied its glands. When a dose of a venom not sufficient to cause immediate death from general effects be given, very rapid and widespread necrosis often may occur in a few hours round the site of inoculation.

An extremely important fact was discovered by Flexner and Noguchi, namely, that the hæmolytic toxin of cobra venom in certain cases has no action by itself, but produces rapid solution of red corpuscles when some normal serum is added, the latter containing a labile complement-like body, which activates the venom. In this there is a close analogy to

what holds in the case of a hæmolytic serum deprived of complement by heat at 55° C. (p. 125). Kyes and Sachs further showed that in addition to serum-complement a substance with definitely known constitution, namely lecithin, had the property of activating the hæmolytic substance in cobra venom, the two apparently uniting to form an actively toxic substance. So far no example of the activation of a bacterial toxin is known, but the results mentioned point to the possibility of this occurring in some cases in the tissues of the body.

There is another group of toxic manifestations which present some analogies to those of the bacterial toxins, but concerning which very little is known. The best example of these is found in the toxic properties of the serum of the eel. If a small quantity of such serum, say ·25 of a c.c., be injected into a rabbit subcutaneously, death occurs in a few minutes. Although nothing is known of the substances giving rise to such effects, the phenomenon is to be considered in relation, on the one hand, to the action of bacterial toxins, and on the other to the phenomenon of anaphylaxis. (See Chapter on Immunity.)

The Theory of Toxic Action.—While we know little of the chemical nature of any toxins, we may, from our knowledge of their properties, group together the tetanus and diphtheria poisons, ricin, abrin, snake poisons, and scorpion poisons. Besides the points of agreement already noted, all possess the further property that, as will be afterwards described, when introduced into the bodies of susceptible animals they stimulate the production of neutralising substances called antitoxins. The nature of the antagonism between toxin and antitoxin will be discussed later. Here, to explain what follows, it may be stated (1) that the molecule of toxin forms directly a combination with the molecule of antitoxin, and (2) that it has been shown that toxin molecules may lose much of their toxic power and still be capable of uniting with exactly the same proportion of antitoxin molecules. From these and other circumstances Ehrlich advanced the view that the toxin molecule has a very complicated structure, and contains two atom groups. One of these, the *haptophorous* (ἅπτειν, to bind to), is that by which combination takes place with the antitoxin molecule, and also with presumably corresponding molecules naturally existing in the tissues. The other atom group he called the *toxophorous*, and it is to this that the toxic effects are due. This atom group is brought into relation with the cell elements, *e.g.*, the nerve cells in tetanus, by the haptophorous group. Ehrlich explained the loss of toxicity which with time occurs in, say, diphtheria toxin, on the theory that the toxophorous group undergoes disintegration. And if we suppose that the haptophorous group remains unaffected we can then understand how a toxin may have its toxicity diminished and still require the same proportion of antitoxin molecules for its neutralisation. To the

bodies whose toxophorous atom groups have become degenerated, Ehrlich gave the name *toxoids*. The theory may afford an explanation of what has been suspected, namely, that in some instances toxins derived from different sources may be related to one another. For example, Ehrlich pointed out that ricin produces in a susceptible animal body an antitoxin which corresponds almost completely with that produced by another vegetable poison, robin (*vide supra*). This may be explained on the supposition that robin is a toxoid of ricin, *i.e.*, their haptophorous groups correspond, while their toxophorous differ. The evidence on which Ehrlich's deductions were based is of a very weighty character, but another view of toxic action is that the relation between a toxin and the cell on which it acts is an example of the physical phenomenon of adsorption. The whole subject will be again referred to in the chapter on Immunity.

With regard to the intracellular toxins we shall see it is difficult to determine whether or not they share with the extracellular poisons the property of stimulating antitoxin formation, —if they do not, then they may belong to an entirely different class of substances. It is certain that immunity against such poisons is difficult to establish and is not of a lasting character. We thus cannot say what the mechanism is by which these poisons act. It may be said that Macfadyen, by grinding up typhoid bacilli frozen by liquid air, claimed that on thawing he obtained the endotoxins in liquid form, and he further stated that by using this fluid he could immunise animals not only against the toxins but also against the living bacteria.

We have already pointed out that those who claim for the aggressins a special character hold that the activity of these bodies has as its effect the interference with the phagocytic functions of the leucocytes. They also hold that a special type of immunity can be developed against the aggressins.

CHAPTER VII.

INFLAMMATORY AND SUPPURATIVE CONDITIONS.

This subject is an exceedingly wide one, and embraces a great many pathological conditions which in their general characters and results are widely different. Thus, in addition to suppuration, various inflammations, ulcerative endocarditis, septicæmia and pyæmia, will come up for consideration. With regard to these, the two following general statements, established by bacteriological research, may be made in introducing the subject. In the first place, there is no one specific organism for any one of these conditions; various organisms may produce them, and not infrequently more than one organism may be present. In the second place, the same organism may produce widely varying results under different circumstances,—at one time a local inflammation or abscess, at another multiple suppurations or a general septicæmia. The principles on which this diversity in results depends have already been explained (p. 174). Furthermore, there are conditions like acute pneumonia, epidemic meningitis, acute rheumatism, etc., which have practically the character of specific diseases, and yet which, as regards their essential pathology, belong to the same class. The arrangement followed below is to a certain extent one of convenience.

It may be well to emphasise some of the chief points in the pathology of these conditions. In *suppuration* the two main phenomena are—(*a*) a progressive immigration of leucocytes, chiefly of the polymorpho-nuclear (neutrophile) variety, and (*b*) a liquefaction or digestion of the supporting elements of the tissue along with necrosis of the cells of the part. The result is that the tissue affected becomes replaced by the cream-like fluid called pus. A suppurative inflammation is thus to be distinguished on the one hand from an inflammation without destruction of tissue, and on the other from necrosis or death *en masse*, where the tissue is not liquefied, and leucocyte

accumulation may be slight. When, however, suppuration is taking place in a very dense fibrous tissue, liquefaction may be incomplete, and a portion of dead tissue or slough may remain in the centre, as is the case in boils. In the case of suppuration in a serous cavity the two chief factors are the progressive leucocytic accumulation and the disappearance of any fibrin which may be present.

Many experiments have been performed to determine whether suppuration can be produced in the absence of micro-organisms by various chemical substances, such as croton oil, nitrate of silver, turpentine, etc.,—care, of course, being taken to ensure the absence of bacteria. The general result obtained by independent observers is that as a rule suppuration does not follow, but that in certain animals and with certain substances it may, the pus being free from bacteria. Buchner showed that suppuration may be produced by the injection of dead bacteria, *e.g.*, sterilised cultures of bacillus pyocyaneus, etc. The subject has now more a scientific than a practical interest, and the general statement may be made that practically all cases of true suppuration met with clinically are due to the action of living micro-organisms.

The term *septicæmia* is applied to conditions in which the organisms multiply within the blood and give rise to symptoms of general poisoning, without, however, producing abscesses in the organs. The organisms are usually more numerous in the capillaries of internal organs than in the peripheral circulation, but the application of the newer methods of cultivation has shown that they can be detected in the peripheral blood much more frequently than was formerly supposed to be the case. The essential fact in *pyæmia*, on the other hand, is the occurrence of multiple abscesses in internal organs and other parts of the body. In most of the cases of typical pyæmia, common in pre-antiseptic days, the starting-point of the disease was a septic wound with bacterial invasion of a vein, leading to thrombosis and secondary embolism. Multiple foci of suppuration may be produced, however, in other ways, as will be described below (p. 215). If the term "pyæmia" be used to embrace all such conditions, the method of their production should always be distinguished.

Bacteria as Causes of Inflammation and Suppuration.

A considerable number of species of bacteria have been found in acute inflammatory and suppurative conditions, and most of these have been proved to be causally related.

Ogston, who was one of the first to study this question (in 1881), found that the organisms most frequently present were micrococci, of which some were arranged irregularly in clusters (staphylococci), whilst others formed chains (streptococci). He found that the former were more common in circumscribed acute abscesses, the latter in spreading suppurative conditions. Rosenbach shortly afterwards (1884), by means of cultures, differentiated several varieties of micrococci, to which he gave the following special names: *staphylococcus pyogenes aureus*, *staphylococcus pyogenes albus*, *streptococcus pyogenes*, *micrococcus pyogenes tenuis*. Other organisms are met with in suppuration, such as *staphylococcus pyogenes citreus*, *staphylococcus cereus albus*, *staphylococcus cereus flavus*, *micrococcus tetragenus*, *pneumococcus*, *pneumobacillus* (Friedländer), *meningococcus*, *bacillus pyogenes fœtidus* (Passet), *bacillus coli communis*, *bacillus lactis aerogenes*, *bacillus pyocyaneus*, *bacillus proteus*, and others. Various anaerobic bacteria are also concerned in the production of an inflammation which is often associated with œdema, hæmorrhage, or necrosis (*vide* Chapter XVII.).

In secondary inflammations and suppurations following acute specific diseases, the corresponding organisms have been found in some cases, such as gonococcus, typhoid bacillus, paratyphoid bacilli, influenza bacillus, etc. Suppuration is also produced by the actinomyces and by the glanders bacillus, and sometimes chronic tubercular lesions have a suppurative character.

Staphylococcus Pyogenes Aureus.—*Microscopical Characters.*—This organism is a spherical coccus about ·9 μ in diameter, which grows irregularly in clusters or masses (Fig. 44). It stains readily with all the basic aniline dyes, and retains the colour in Gram's method (Plate I., Fig. 1).

Cultivation.—It grows readily in all the ordinary media at the room temperature, though much more rapidly at the temperature of the body. In stab cultures in *peptone gelatin* a streak of growth is visible on the day after inoculation, and on the second or third day liquefaction commences at the top. As liquefaction proceeds, the growth falls to the bottom as a flocculent deposit, which soon assumes a bright yellow colour, while a yellowish film may form on the surface, the fluid portion still remaining turbid. Ultimately liquefaction extends out to the wall of the tube (Fig. 45). In *gelatin plates* colonies may be seen with the low power of the microscope in twenty-four hours, as little balls somewhat granular on the surface and of brownish colour. On the second day they are visible to the

naked eye as whitish yellow points, which in typical strains afterwards become more distinctly yellow. Liquefaction occurs around these, and little cups are formed, at the bottom of which the colonies form little yellowish masses. On *agar*, a stroke

a *b*

FIG. 45.—Two stab cultures of staphylococcus pyogenes aureus in gelatin, (*a*) 10 days old, (*b*) 3 weeks old, showing liquefaction of the medium and characters of growth. Natural size.

culture forms a line of abundant yellowish growth, with smooth, shining surface, well formed after twenty-four hours at 37° C. Later it becomes bright orange in colour, and resembles a streak of oil paint. Single colonies on the surface of agar are circular discs of similar appearance, which may reach 2 mm. or more in diameter. On *potato* it grows well at ordinary temperature, forming a somewhat abundant layer of orange colour. In *bouillon* it produces a uniform turbidity, which afterwards settles to the bottom as an abundant layer and assumes a brownish-yellow tint. In the various media it renders the reaction acid, and it coagulates milk, in which it readily grows. The cultures have a somewhat sour odour. It has considerable tenacity of life outside the body, cultures in gelatin often being alive after having been kept for several months.

The staphylococcus pyogenes albus is similar in character, with the exception that its growth on all the media is white. The colour of the staphylococcus aureus may become less distinctly yellow after being kept for some time in culture, but it never assumes the white colour of the staphylococcus albus, and it has not been found possible to transform the one organism into the other. A micrococcus called by Welch *staphylococcus epidermidis albus* is practically always present in the skin epithelium; it is distinguished by its relatively non-pathogenic properties and by liquefying gelatin somewhat slowly. It is probably an attenuated variety of the staphylococcus albus.

The *staphylococcus pyogenes citreus*, which is less frequently met with, differs in the colour of the cultures, being a lemon yellow, and is usually less virulent than the other two.

The *staphylococcus cereus albus* and *staphylococcus cereus flavus* are of much less importance. They produce a wax-like growth on gelatin without liquefaction; hence their name.

Streptococcus pyogenes.—This organism (Plate I., Fig. 1) is a coccus of slightly larger size than the staphylococcus aureus, about 1 μ in diameter, and forms chains which may contain a large number of members, especially when it is growing in fluids (Fig. 46). The chains vary somewhat in length in different specimens, and on this ground varieties have been distinguished, *e.g.*, the *streptococcus brevis* and *streptococcus longus* (*vide infra*). As division may take place in many of the cocci in a chain at the same time, the appearance of a chain of diplococci is often met with. In young cultures the cocci are fairly uniform in size, but after a time they present considerable variations, many swelling up to twice their normal diameter. These are to be regarded as involution forms. In its staining reactions the streptococcus resembles the staphylococci described, being readily coloured by Gram's method.

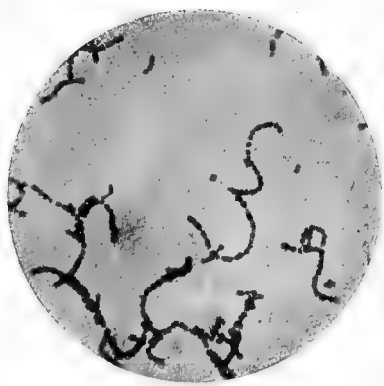

FIG. 46.—Streptococcus pyogenes, young culture on agar, showing chains of cocci. Stained with weak carbol-fuchsin. ×1000.

Cultivation.—In cultures outside the body the streptococcus pyogenes grows much more slowly than the staphylococci, and also dies out more readily, being in every respect a more delicate organism.

In *peptone gelatin* a stab culture shows, about the second day, a thin line, which in its subsequent growth is seen to be formed of a row of minute rounded colonies of whitish colour, which may be separate at the lower part of the puncture. They do not usually exceed the size of a small pin's head, this size being reached about the fifth or sixth day. The growth does not spread on the surface, and no liquefaction of the medium occurs. The colonies in gelatin plates have a corresponding appearance, being minute spherical points of whitish colour. A somewhat warm temperature is necessary for growth; even at 20° C. some varieties do not grow. On the *agar* media, growth takes place along the stroke as a collection of small circular discs of semi-translucent appearance, which show a great tendency to remain separate (Fig. 47). The separate colonies remain small, rarely exceeding 1 mm. in diameter. Under a low power of the microscope they have a slightly woolly margin. Cultures on agar kept at the body temperature may often be found to be dead after ten days. On *potato*, as a rule, no visible growth takes place. In *milk* it produces a strongly acid reaction but no clotting of the medium. It ferments lactose, saccharose, and salicin (Andrewes and Horder); it produces no fermentation of inulin in Hiss's serum-water-medium, in this respect differing from the pneumococcus. It has usually a strong hæmolytic action, as can be demonstrated by growing it in blood-agar plates (p. 45). In *bouillon*, growth forms numerous minute granules which afterwards fall to the bottom, the deposit, which is usually not very abundant, having a sandy appearance. The appearance in broth, however, presents variations which have been used as an aid to distinguish different species of streptococci. It has been found that those which form

FIG. 47.—Culture of the streptococcus pyogenes on an agar plate, showing numerous colonies—three successive strokes. Twenty-four hours' growth. Natural size.

the longest chains grow most distinctly in the form of spherical granules, those forming short chains giving rise to a finer deposit. To a variety which forms distinct spherules of minute size the term *streptococcus conglomeratus* has been given.

Varieties of Streptococci.—Formerly the *streptococcus pyogenes* and the *streptococcus erysipelatis* were regarded as two distinct species, and various points of difference between them were given. Further study, and especially the results obtained by modifying the virulence (p. 175), have shown that these distinctions cannot be maintained, and now practically all authorities are agreed that the two organisms are one and the same, erysipelas being produced when the streptococcus pyogenes of a certain standard of virulence gains entrance to the lymphatics of the skin. Petruschky, moreover, showed conclusively by inoculation that a streptococcus cultivated from pus could cause erysipelas in the human subject.

Streptococci have also been classified according to the length of the chains. Thus there have been distinguished (*a*) *streptococcus longus*, which occurs in long chains and is pathogenic to rabbits and mice; (*b*) *streptococcus brevis*, which is common in the mouth in normal conditions, and is usually non-pathogenic; and (*c*) *streptococcus conglomeratus*, so called from its forming in bouillon minute granules composed of very long chains. French writers describe a short-chained variety under the title *enterococcus*; this for convenience will be described separately. It may be stated that pathogenic streptococci obtained from the human subject usually form fairly long chains on agar, whilst the short streptococci obtained from the mouth and intestine are usually devoid of virulence. But to these statements exceptions occur, as short streptococci may be associated with grave lesions, and long streptococci without virulence may be obtained on normal mucous membranes. Recently anaerobic streptococci have been isolated from war wounds (Fleming). In view of all the facts, pathogenicity and morphology cannot be taken as affording in themselves a basis of classification. Accordingly, other methods have been introduced as a means of differentiation, and of these the most important are fermentation and hæmolytic tests.

Fermentation.—Mervyn Gordon introduced for this purpose nine tests, namely: (1) The clotting of milk, (2) the reduction of neutral-red, (3–9) the fermentation with acid production of saccharose, lactose, raffinose, inulin, salicin, coniferin, and mannite. Andrewes and Horder by means of these have differentiated six varieties, of which five occur in the human subject. These are: (*a*) A short-chained form called *streptococcus mitis*, which occurs chiefly in the saliva and fæces as a saprophyte. It ferments

saccharose and lactose, and sometimes the glucosides; it produces an acid reaction in milk but no clotting, and often reduces neutral-red. (*b*) The *streptococcus pyogenes*, which is the most important pathogenic variety, and has the characters described above. (*c*) The *streptococcus salivarius*, which corresponds to the streptococcus brevis of the mouth, and which, as regards fermentative action, seems to bear the same relation to the next variety as the streptococcus mitis does to the streptococcus pyogenes. It ferments saccharose, lactose, and raffinose, sometimes the glucosides and rarely inulin; it clots milk and reduces neutral-red. (*d*) The *streptococcus anginosus*, which corresponds with the so-called streptococcus scarlatinæ and the streptococcus conglomeratus. It ferments saccharose and lactose, and sometimes raffinose, reduces neutral-red, and is actively hæmolytic. It usually clots milk and does not grow on gelatin at 20° C. (*e*) The *streptococcus fæcalis*, a short-chained form, which abounds in the intestine and which has great fermentative activity, and reacts positively to all Gordon's tests with the exception of raffinose and inulin. It forms sulphuretted hydrogen, and is devoid of hæmolytic action. (*f*) The sixth variety is the *streptococcus equinus*, which is common in the air and dust of towns, and appears to be derived from horse dung.[1] It ferments saccharose and the two glucosides, and forms little or no acid in milk. It is, however, to be noted that to all these varieties variants are met with.

Gordon has summarised as follows the chief features of the three most important pathogenic streptococci:

	Neutral-Red.	Raffinose.	Mannite.
Str. pyogenes . .	−	−	?
Str. salivarius .	+	+	−
Str. fæcalis	+	−	+

Ainley Walker in studying this question, however, has found that various strains of streptococci show considerable variability in their fermentative powers when kept for some time under ordinary conditions of growth, and Beattie and Yates have observed corresponding changes when streptococci are passed through the animal body. Nevertheless fermentative activity has been generally accepted as of great service in classification, especially when the organisms have been recently isolated.

Hæmolysis (*vide* also p. 202).—Schottmüller has employed the appearance of the colonies of streptococci on blood agar as a means of separating varieties. The medium used by him consisted of two parts human blood (rabbit blood may likewise be used) and five parts melted agar; it is, however, better to add the blood in the proportion of 5–10 per cent. He distinguished the *streptococcus longus* or *erysipelatis*, which forms grey colonies and has a marked hæmolytic action; a *streptococcus mitior* or *viridans*, a short-chained organism, which produces small green colonies and very little hæmolysis; and a *streptococcus mucosus encapsulatus*, which, as its name indicates, shows well-marked capsules and produces colonies which have a slimy consistence. Mandelbaum adds to these the

[1] For further details, reference must be made to the original papers, *Lancet*, September 1906, ii. 708, etc.

streptococcus saprophyticus, which is without hæmolytic action. It should be noted that on blood agar the pneumococcus forms green colonies and produces little or no hæmolysis. Levy finds that a 2·5 per cent. solution of taurocholate of sodium in bouillon produces complete bacteriolysis of the pneumococcus and the streptococcus mucosus, while it has no effect on other varieties of streptococcus. He considers the streptococcus mucosus to be a variety of pneumococcus. On the other hand, some strains of streptococcus mucosus have been found to be insoluble in bile-salts; hence two varieties have been distinguished (*vide* p. 231). The general statement may be made that most of the streptococci from lesions in the human subject have hæmolytic action, but that occasionally streptococci without this property are found even in severe infections.

A combination of fermentative and hæmolytic tests has also been used in classification, and this appears advisable. For example, Holman takes the presence or absence of hæmolysis as the first basis of classification. The two groups thus obtained are subdivided into four, according to the action on lactose; these again into eight, according to the action on mannite; and finally these into sixteen, according to the effect on salicin. Blake employs the same principle but omits mannite, and does not subdivide the hæmolytic group.

On the whole, there may be said to be substantial agreement in the results of those who have systematically used fermentation tests. In the description of any strain these should be taken along with other characters—morphology, growth conditions, pathogenicity, hæmolytic and fermentative effects, solubility or non-solubility in bile-salts, etc.

At present no definite opinion can be expressed as to the etiological relation of streptococci to scarlet fever; we can only say that streptococci are almost invariably present in the fauces, and that to them many of the complications of the disease are due. The streptococcus conglomeratus (anginosus) is specially abundant as a rule, though it also occurs in other acute catarrhal states. In fact, Gordon found that the types of streptococci in the throat in scarlet fever corresponded with those met with in normal conditions. Mair has recently isolated an organism to which he has given the name *diplococcus scarlatinæ*; he obtained it from the throat in over 80 per cent. of cases of scarlet fever. It is an oval coccus occurring usually in pairs like the pneumococcus, and, as it is soluble in bile salts and ferments inulin, is rather to be classified with that organism. Most strains fail to grow on agar or in bouillon without the presence of serum. From experiments on monkeys and on other grounds he considers that it probably has an etiological relationship to the disease.

Enterococcus.—This variety, when growing in the tissues, usually occurs as a diplococcus, the individual organisms being rounded or oval, and the members of a pair being often set at an angle, and unequal in size; sometimes there is indication of a capsule. In cultures it shows considerable pleomorphism, and tends to grow in masses, though short

chains occur in fluid media. On the surface of agar it produces a thin, semi-transparent layer with smooth margins, and there is not the tendency to form separate colonies which is shown by most streptococci. In a corresponding way it forms a diffuse turbidity in bouillon, with the formation after a time of a somewhat glairy deposit; sometimes there is a scum on the surface. It flourishes well at a lower temperature than that at which the streptococcus pyogenes will grow, and has great longevity in cultures. When first isolated, some strains have been found to prefer anaerobic conditions. It has very active fermentative properties and coagulates milk; probably it is the same variety as the streptococcus fæcalis described above. It is non-hæmolytic and relatively non-virulent, in fact most strains can be injected in large doses without pathogenic effects. It is a normal inhabitant of the intestine, and has been found to appear in the intestine of the infant shortly after birth. The lesions in which it is found are chiefly those where infection can be traced from the bowel. It is practically always present in contaminated gun-shot wounds at an early stage (*vide* p. 441), gradually disappearing at a later stage. It has been found in abscesses following typhoid, and not infrequently in the bladder during or after bowel infections, though also apart from these. It has been obtained during the war from the blood and bladder in a fair proportion of cases of septicæmic type, in others where myalgia was the chief feature, in others again of the type of "trench fever." (Houston and McCloy.)

Toxins of Pyococci.—As stated above, many streptococci have a distinct hæmolytic action, and this is due to the production of a toxin which is largely extra-cellular. The amount of hæmolysin formed varies greatly in the case of different strains and also according to the medium used. McLeod recommends a medium composed of 20 per cent. horse serum and 80 per cent. peptone bouillon with distinctly alkaline reaction, and has found a Maasen filter to be specially suitable for obtaining the hæmolytic filtrate. In the medium mentioned the maximum formation of hæmolysin is reached in about eighteen hours, and thereafter a diminution occurs. The hæmolysin is very labile, being destroyed at 55° C., and rapidly deteriorating even when kept in the incubator for a few hours. The filtrate has also a toxic action on the tissues, producing focal necrosis especially in the liver of the rabbit. It is also a noteworthy fact that an antitoxin to the hæmolysin cannot be obtained. Streptococcus viridans, though producing little or no lysis, has the property of forming methæmoglobin from hæmoglobin. The staphylococcus aureus and staphylococcus albus also produce hæmolysins, which so far as can be judged by their properties are identical. (The staphylococcus epidermidis albus, however, produces no hæmolysin.) The staphylolysin, which can readily be obtained by filtration, though more stable than the streptolysin, is also destroyed at a temperature of 55° C. It, however, differs from the latter, inasmuch as an antitoxin can readily be

obtained to it; in fact, in its properties it presents a close analogy to the toxins of diphtheria and tetanus. The two staphylococci mentioned also produce a toxin which kills leucocytes, and is therefore called "leucocidin" (van de Velde). This toxin can be obtained by filtration of fluid cultures, and on being injected into animals leads to the formation of an antitoxin. Apparently the same leucocidin is produced by the staphylococcus aureus and staphylococcus albus.

Micrococcus tetragenus.—This organism, first described by Gaffky, is characterised by the fact that it divides in two planes at right angles to one another (Fig. 48), and is thus generally found in the tissues in groups of four, or tetrads, which are often seen to be surrounded by a capsule. The cocci measure 1 μ in diameter. They stain readily with all the ordinary stains, and also retain the stain in Gram's method.

It grows readily on all the media at the room temperature. In a puncture culture on peptone-gelatin a pretty thick whitish line forms along the track of the needle, whilst on the surface there is a thick rounded disc of whitish colour. The gelatin is not liquefied. On the surface of agar and of potato the growth is an abundant moist layer of the same colour. The growth on all the media has a peculiar viscid or tenacious character, owing to the gelatinous character of the sheaths of the cocci.

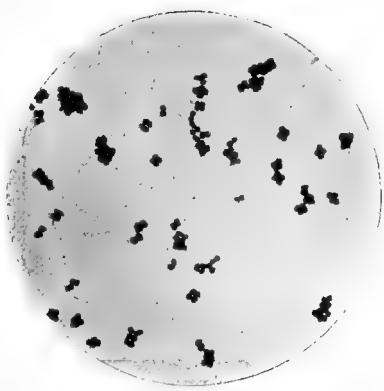

FIG. 48.—Micrococcus tetragenus; young culture on agar, showing tetrads. Stained with weak carbol-fuchsin. ×1000.

White mice are exceedingly susceptible to this organism. Subcutaneous injection is followed by a general septicæmia, the organism being found in large numbers in the blood throughout the body. Guinea-pigs are less susceptible; sometimes only a local abscess with a good deal of necrotic change results; sometimes there is also septicæmia.

Bacillus coli communis.—The microscopic and cultural characters are described in the chapter on Typhoid Fever. The *bacillus lactis aerogenes* and the *bacillus pyogenes fœtidus* closely resemble it; they are either varieties or closely related species. The former is distinguished by producing more abundant gas formation, and by its growth on gelatin, etc., being thicker and whiter than that of the bacillus coli.

Bacillus proteus.—The term proteus has been applied to a group of intestinal bacteria, of which several varieties have been described, *e.g.*, *vulgaris, mirabilis, zenkeri, capsulatus*; the "urobacillus septicus" is also a variety of proteus. They are characterised by their pleomorphism, hence the name, and by the rapid liquefaction of gelatin which they produce. Proteus vulgaris has the following characters: It is a small

bacillus of about the size of b. coli, straight or slightly curved, but coccoid and filamentous forms also occur, and a marked tendency to involution forms is to be noted. It is actively motile, and possesses numerous lateral flagella ; it does not form spores. It stains readily with basic dyes and is Gram-negative. It grows readily on all the ordinary media at room temperature, but best at the body temperature. In a gelatin stab culture liquefaction appears within twenty-four hours ; it spreads rapidly in the form of a funnel, and ultimately the whole medium is liquefied and presents a turbid appearance. On gelatin plates the characters are somewhat peculiar, especially when 5 per cent. gelatin is used. The colonies are at first small spheres with granular centre and peripheral radiation extending into the medium ; liquefaction soon follows, and from the superficial colonies offshoots extend over the medium in tendril-like fashion, these being composed of bacilli in chains placed side by side. Groups of bacilli may also become separate, move over the surface of the medium, and form growths at a distance,—the so-called "swarm-colonies." On an agar slope the organism forms a moist layer, which extends over the whole surface of the medium ; in this way, the bacillus can readily be separated from other organisms present along with it. On potato it forms a slimy film with some discoloration around it. It coagulates milk without acid reaction. The organism is actively proteolytic and forms sulphuretted hydrogen, reduces nitrates to nitrites, and ultimately to ammonia, and splits urea. It forms acid and gas from glucose and mannite, but its action on other sugars seems to vary. Although some cases of pure proteus infection have been described, *e.g.*, in pleurisy, the bacilli generally occur along with other organisms in septic inflammations, such as cystitis and pyelitis, endometritis, peritonitis, etc. Proteus organisms are also common in gun-shot and other contaminated wounds. Cases of severe gastro-enteritis apparently due to proteus have also been described (Horowitz).

Bacillus pyocyaneus.—This organism occurs in the form of minute rods 1·5 to 3 μ in length and less than ·5 μ in thickness (Fig. 49). Occasionally two or three are found attached end to end. It is actively motile, possessing a terminal flagellum, and does not form spores. It stains readily with the ordinary basic stains, but is decolorised by Gram's method.

Cultivation.—It grows readily on all the ordinary media at the room temperature, the cultures being distinguished by the formation of a greenish pigment. In puncture cultures in peptone-gelatin a greyish line appears in twenty-four hours, and at its upper part a small cup of liquefaction forms within forty-eight hours. At this time a slightly greenish tint is seen in the superficial part of the gelatin. The liquefaction extends pretty rapidly, the fluid portion being turbid and showing masses of growth at its lower part. The green colour becomes more and more marked, and diffuses through the gelatin. Ultimately liquefaction reaches the wall of the tube. In plate cultures the colonies appear as minute whitish points, those on the surface being the larger. Under a low power of the microscope they have a brownish-yellow colour and show a nodulated surface, the superficial colonies being thinner and larger. Liquefaction soon occurs, the colonies on the surface forming shallow cups with small irregular masses of growth at the bottom, the deep colonies small spheres of liquefaction. Around the colonies a greenish tint appears. On agar the growth forms an abundant slimy greyish layer which afterwards becomes greenish, and a bright green colour diffuses

through the whole substance of the medium. On potatoes the growth is an abundant reddish-brown layer resembling that of the glanders bacillus, and the potato sometimes shows a greenish discoloration.

From the cultures there can be extracted by chloroform a coloured body, pyocyanin, which belongs to the aromatic series, and crystallises in the form of long, delicate bluish-green needles. On the addition of a weak acid its colour changes to a red.

This organism has distinct pathogenic action in certain animals. Subcutaneous injection of small doses in rabbits may produce a local suppuration, but if the dose be large, spreading hæmorrhagic œdema results, which may be attended by septicæmia. Intravenous injection may produce, according to the dose, rapid septicæmia with nephritis, or sometimes a more chronic condition of wasting attended by albuminuria.

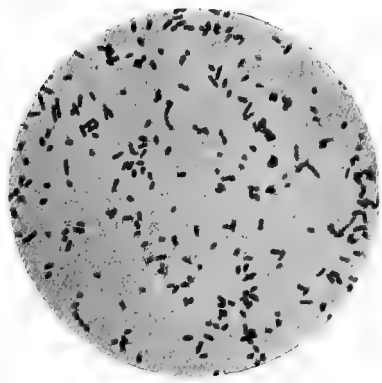

FIG. 49.—Bacillus pyocyaneus; young culture on agar. Stained with weak carbol-fuchsin. ×1000.

Experimental Inoculation.—We shall consider chiefly the staphylococcus pyogenes aureus and the streptococcus pyogenes, as these have been most fully studied.

It may be stated at the outset that the occurrence of suppuration depends upon the number of organisms introduced into the tissues, the number necessary varying not only in different animals, but also in different parts of the same animal,—a smaller number producing suppuration in the anterior chamber of the eye, for example, than in the peritoneum. The virulence of the organism also may vary, and corresponding results may be produced. Especially is this so in the case of the streptococcus pyogenes.

The *staphylococcus aureus*, when injected *subcutaneously* in suitable numbers, produces an acute local inflammation, which is followed by suppuration, in the manner described above. If a large dose is injected, the cocci may enter the blood stream in sufficient numbers to cause secondary suppurative foci in internal organs (*cf.* intravenous injection).

Intravenous injection in rabbits, for example, produces interesting results, which vary according to the quantity used. If

a relatively small quantity be used, the cocci gradually disappear from the circulating blood; some become destroyed, while others settle in the capillary walls in various parts and produce minute abscesses. These are most common in the kidneys, where they occur both in the cortex and medulla as minute yellowish areas surrounded by a zone of intense congestion and hæmorrhage. Similar small abscesses may be produced in the heart wall, in the liver, under the periosteum and in the interior of bones, and occasionally in the striped muscles. Very rarely indeed, in experimental injection, do the cocci settle on the healthy valves of the heart. If, however, when the organisms are injected into the blood, there be any traumatism of a valve, or of any other part of the body, they show a special tendency to settle at these weakened points.

Experiments on the *human subject* have also proved the pyogenic properties of those organisms. Garré inoculated scratches near the root of his finger-nail with a pure culture, a small cutaneous pustule resulting; and by rubbing a culture over the skin of the forearm he caused a carbuncular condition which healed only after some weeks. Confirmatory experiments of this nature were made by Bockhart, Bumm, and others.

When tested experimentally, the staphylococcus pyogenes albus has practically the same pathogenic effects as the staphylococcus aureus.

The *streptococcus pyogenes* is an organism the virulence of which varies much according to the diseased condition from which it has been obtained, and also one which loses its virulence rapidly in cultures. Even highly virulent cultures, if grown under ordinary conditions, in the course of time lose practically all pathogenic power. By passage from animal to animal, however, the virulence may be much increased, and *pari passu* the effects of inoculation are correspondingly varied. Marmorek, for example, found that the virulence of a streptococcus can be enormously increased by growing it alternately (*a*) in a mixture of human blood serum and bouillon (*vide* p. 42), and (*b*) in the body of a rabbit; ultimately, after several passages it possesses a super-virulent character, so that even an extremely minute dose introduced into the tissues of a rabbit produces acute septicæmia, with death in a few hours. It has been proved by Marmorek's experiments, and those of others, that the same species of streptococcus may produce at one time merely a passing local redness, at another a local suppuration, at another

a spreading erysipelatous condition, or again a general septicæmic infection, according as its virulence is artificially increased. Such experiments are of extreme importance as explaining to some extent the great diversity of lesions in the human subject with which streptococci are associated.

Bacillus Coli Communis.—The virulence of this organism also varies much, and can be increased by passage from animal to animal. Injection into the serous cavities of rabbits produces a fibrinous inflammation which becomes purulent if the animal lives sufficiently long. If, however, the virulence of the organism be of a high order, death takes place before suppuration is established, and there is a septicæmic condition, the organisms occurring in large numbers in the blood. Intravenous injection of a few drops of a virulent bouillon culture usually produces a rapid septicæmia with scattered hæmorrhages in various organs.

Lesions in the Human Subject.—The following statement may be made with regard to the occurrence of the chief organisms mentioned, in the various suppurative and inflammatory conditions in the human subject. The account is, however, by no means exhaustive, as clinical bacteriology has shown that practically every part of the body may be the site of a lesion produced by the pyogenic bacteria. It may also be noted that acute catarrhal conditions of cavities or mucous surfaces are in many cases also to be ascribed to their presence.

The *staphylococci* are the most common causal agents in localised abscesses, in pustules on the skin, in carbuncles, boils, etc., in acute suppurative periostitis; they also occur frequently in catarrhs of mucous surfaces, in ulcerative endocarditis, and in various pyæmic conditions. They may also be present in cases of septicæmia.

Streptococci are especially found in spreading inflammation with or without suppuration; in diffuse phlegmonous and erysipelatous conditions, suppuration in serous membranes and in joints (Fig. 50). They are usually to be found in gun-shot wounds; at first the "enterococcus" abounds, at a later stage streptococcus pyogenes is the more common type. They also occur in acute suppurative periostitis and ulcerative endocarditis. Secondary abscesses in lymphatic glands and lymphangitis are also, we believe, more frequently caused by streptococci than staphylococci. They also produce fibrinous exudation on the mucous surfaces, leading to the formation of false membrane in many of the cases of non-diphtheritic inflammation of the

throat, which are met with in scarlatina [1] and other conditions, and they are also the organisms most frequently present in acute catarrhal inflammations in this situation. In puerperal peritonitis they are frequently found in a condition of purity, and they also appear to be the most frequent cause of puerperal septicæmia. In a certain proportion of cases they also produce peritonitis secondary to appendicitis. In pyæmia they are frequently present, though in most cases associated with other pyogenic organisms. Some cases of enteritis in infants—streptococcus enteritis—are also apparently due to a streptococcus, which is usually of the "enterococcus" type.

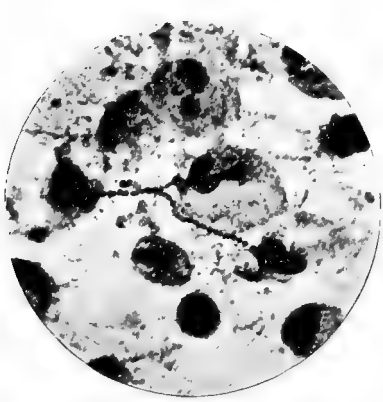

FIG. 50.—Streptococci in acute suppuration. Corrosive film; stained by Gram's method and safranin. × 1000.

The *bacillus coli communis* is found in a great many inflammatory and suppurative conditions in connection with the alimentary tract—for example, in suppuration in the peritoneum, or in the extraperitoneal tissue with or without perforation of the bowel, in the peritonitis following strangulation of the bowel, in appendicitis and the lesions following it, in suppuration in and around the bile ducts, etc. It may also occur in lesions in other parts of the body, — endocarditis, pleurisy, etc., which in some cases are associated with lesions of the intestine, though in others such cannot be found. It is also frequently present in inflammation of the urinary passages, cystitis, pyelitis, abscesses in the kidneys, etc., these lesions being in fact most frequently caused by this or closely allied organisms.

In certain cases of enteritis it is probably the causal agent, though this is difficult of proof, as it is much increased in numbers in practically all abnormal conditions of the intestine. We may remark that it has been repeatedly proved that the bacillus coli cultivated from various lesions is more virulent than

[1] True diphtheria may also occasionally be associated with this disease usually as a sequel.

the ordinary intestinal strain, its virulence having been heightened by growth in the tissues.

The *micrococcus tetragenus* is often found in suppurations in the region of the mouth or in the neck, and also occurs in various lesions of the respiratory tract, in phthisical cavities, abscesses in the lungs, etc. Sometimes it is present alone, and probably has a pyogenic action in the human subject under certain conditions. In other cases it is associated with other organisms. During the war, cases of general infection along with pneumonic symptoms have been recorded in soldiers, the organism having been isolated from the blood; recovery has been the rule. Cases of pyæmia have been described in which this organism was found in a state of purity in the pus in various situations. In this latter condition the pus has been described as possessing an oily, viscous character, and as being often blood-stained.

The *bacillus pyocyaneus* is rarely found alone in pus, though it is not infrequent along with other organisms. We have met with it several times in cases of multiple abscesses, in association with the staphylococcus pyogenes aureus. It is present along with other organisms in a large proportion of old suppurating war wounds. Lately some diseases in children have been described in which the bacillus pyocyaneus has been found throughout the body; in these cases the chief symptoms have been fever, gastro-intestinal irritation, pustular or petechial eruptions in the skin, and general marasmus. It has also been said to be constantly present in pemphigus, and it certainly occurs in some cases of this disease. It sometimes occurs in cystitis and pyelitis.

Inflammatory and suppurative conditions, associated with the organisms of special diseases, will be described in the respective chapters.

Mode of Entrance and Spread.—Many of the organisms described have a wide distribution in nature, and many also are present on the skin and mucous membranes of healthy individuals. The entrance of these organisms into the deeper tissues when a surface lesion occurs can be readily understood. Their action will, of course, be favoured by any condition of depressed vitality. Though in normal conditions the blood is bacterium-free, we must suppose that from time to time a certain number of such organisms gain entrance to it from trifling lesions of the skin or mucous surfaces, the possibilities of entrance from the latter being especially numerous. In most cases they are killed by the action of the healthy serum or cells of the body,

and no harm results. If, however, there be a local weakness, they may settle in that part and produce suppuration, and from this other parts of the body may be infected. Such a supposition as this is necessary to explain many inflammatory and suppurative conditions met with clinically. In some cases of multiple suppurations due to staphylococcus infection, only an apparently unimportant surface lesion is present; whilst in others no lesion can be found to explain the origin of the infection. The term

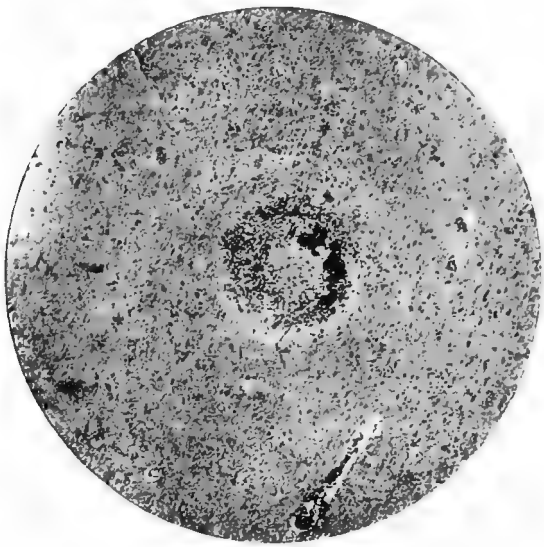

FIG. 51.—Minute focus of commencing suppuration in brain—case of acute ulcerative endocarditis. In the centre a small hæmorrhage; to right side dark masses of staphylococci; zone of leucocytes at periphery.

Alum carmine and Gram's method. × 50.

cryptogenetic has been applied by some writers to such cases in which the original point of infection cannot be found, but its use is scarcely necessary.

The paths of secondary infection may be conveniently summarised thus: First, by lymphatics; in this way the lymphatic glands may be infected, and also serous sacs in relation to the organs where the primary lesion exists. Second, by natural channels, such as the ureters and the bile ducts, the spread being generally associated with an inflammatory condition of the

lining epithelium. In this way the kidneys and liver respectively may be infected. Third, by the blood vessels: (*a*) by a few organisms gaining entrance to the blood from a local lesion, and settling in a favourable nidus or a damaged tissue, the original path of infection often being obscure; (*b*) by a septic phlebitis with suppurative softening of the thrombus and resulting embolism; and we may add (*c*), by a direct extension along a vein,

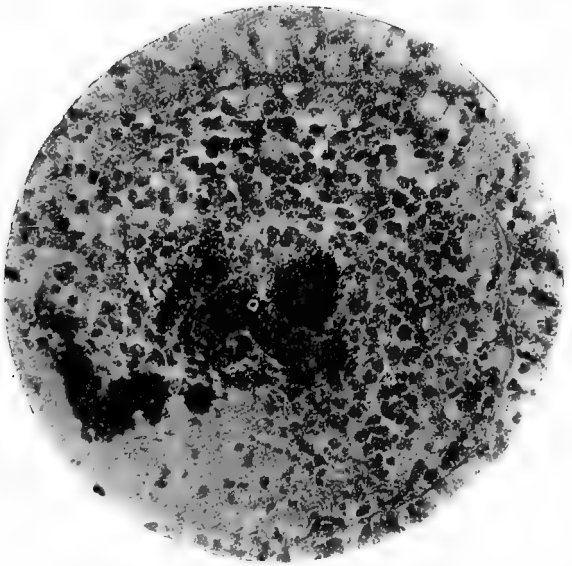

FIG. 52.—Secondary infection of a glomerulus of kidney by the staphylococcus aureus, in a case of ulcerative endocarditis. The cocci (stained darkly) are seen plugging the capillaries and also lying free. The glomerulus is much swollen, infiltrated by leucocytes, and partly necrosed.
Paraffin section; stained by Gram's method and Bismarck-brown. ×300.

producing a spreading thrombosis and suppuration within the vein. In this way suppuration may spread along the portal vein to the liver from a lesion in the alimentary canal, the condition being known as pylephlebitis suppurativa.

Although many of the lesions produced by the bacteria under consideration have already been mentioned, certain conditions may be selected for further consideration on account of their clinical importance or bacteriological interest.

Endocarditis.—There is now strong evidence that all cases of acute endocarditis are due to bacterial infection. In the simple or vegetative form, so often the result of acute rheumatism, the micrococcus rheumaticus (p. 221) has been cultivated from the valves in a certain number of cases, and is probably the causal agent in most instances.

Endocarditis of the ulcerative type may be produced by

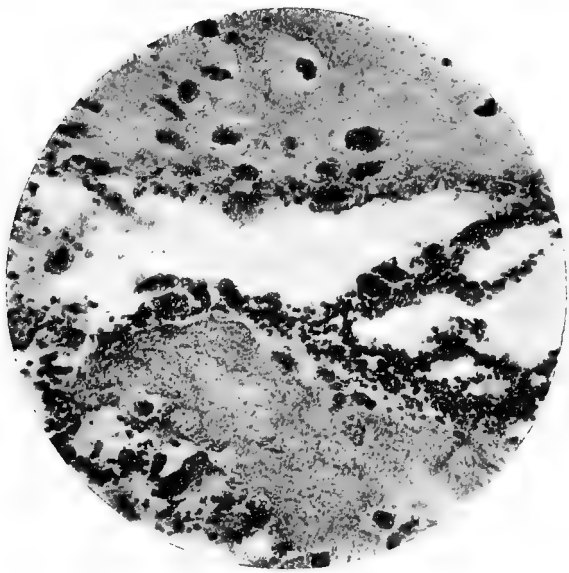

FIG. 53.—Section of a vegetation in ulcerative endocarditis showing numerous staphylococci lying in the spaces. The lower portion is a fragment in process of separation.
Stained by Gram's method and Bismarck-brown. ×600.

various organisms, chiefly pyogenic. Of these the streptococci and staphylococci are most frequently found; the former producing less destructive changes, the formation of abundant vegetations being not uncommon. In the case of streptococcic infection we meet with all degrees of severity, and in view of the bacteriological results rheumatic endocarditis is probably to be regarded merely as the mildest example. In some cases of ulcerative endocarditis following pneumonia the pneumococcus (Fraenkel's) is present; in these the vegetations often reach a

large size and have not so much tendency to break down as in the case of staphylococcus infections. Other organisms have been cultivated from different cases of the disease, and some of these have received special names; for example, the diplococcus endocarditidis encapsulatus, bacillus endocarditidis griseus (Weichselbaum), and others. In some cases the bacillus coli has been found, and occasionally in endocarditis following typhoid the typhoid bacillus has been described as the organism present. The meningococcus and also the gonococcus have been shown to affect the heart valves (p. 262), though such occurrences are relatively rare. Tubercle nodules on the heart valves have been found in a few cases of acute tuberculosis, though no vegetative or ulcerative condition is usually produced.

Experimental.—Occasionally ulcerative endocarditis is produced by the simple intravenous injection of staphylococci and streptococci into the circulation, but this is a very rare occurrence. It often follows, however, when the valves have been previously injured. Orth and Wyssokowitsch at a comparatively early date produced the condition by damaging the aortic cusps by a glass rod introduced through the carotid, and afterwards injecting staphylococci into the circulation. Similar experiments have since been repeated with streptococci, pneumococci, and other organisms, with like result. Ribbert found that if a potato culture of the staphylococcus aureus were rubbed down in salt solution so as to form an emulsion, and then injected into the circulation, some minute fragments became arrested at the attachment of the chordæ tendineæ and produced an ulcerative endocarditis.

Acute Suppurative Periostitis and Osteomyelitis.—Special mention is made of this condition on account of this comparative frequency and gravity. The great majority of cases are caused by the pyogenic cocci, of which one or two varieties may be present, the staphylococcus aureus, however, occurring most frequently. Pneumococci have been found alone in some cases, and in a considerable number of cases following typhoid fever the bacillus typhosus has been found alone. In others, again, the bacillus coli is present.

The affection of the periosteum or interior of the bones by these organisms, which is especially common in young subjects, may take place in the course of other affections produced by the same organisms or in the course of infective fevers, but in a great many cases the path of entrance cannot be determined. In the course of this disease serious secondary infections are always very liable to follow, such as small abscesses in the kidneys, heart-wall, lungs, liver, etc., suppurations in serous cavities, and ulcerative endocarditis; in fact, some cases present the most typical examples of extreme general staphylococcus

infection. The entrance of the organisms into the blood stream from the lesion of the bone is especially favoured by the arrangement of the veins in the bone and marrow.

Experimental.—Multiple abscesses in the bones and under the periosteum may occur in simple intravenous injection of the pyogenic cocci into the blood, and are especially liable to be formed when young animals are used. These abscesses are of small size, and do not spread in the same way as in the natural disease in the human subject.

In experiments on healthy animals, however, the conditions are not analogous to those of the natural disease. We must presume that in the latter there is some local weakness or susceptibility, which enables the few organisms which have reached the part by the blood to settle and multiply. Moreover, if a bone be experimentally injured, *e.g.*, by actual fracture or by stripping off the periosteum before the organisms are injected, then a much more extensive suppuration occurs at the injured part.

Erysipelas.—A spreading inflammatory condition of the skin may be produced by a variety of organisms, but the disease in the human subject in its characteristic form is almost invariably due to a streptococcus, as was shown by Fehleisen in 1884. He obtained pure cultures of the organism, and gave it the name of streptococcus erysipelatis; and, further, by inoculations on the human subject as a therapeutic measure in malignant disease, he was able to reproduce erysipelas. As stated above, however, one after another of the supposed points of difference between the streptococcus of erysipelas and the streptococcus pyogenes of suppuration has broken down. It must be noted, however, that erysipelas passes from patient to patient as erysipelas, and purulent conditions due to streptococci do not appear liable to be followed by erysipelas. On the other hand, the connection between erysipelas and puerperal septicæmia is well established clinically.

In a case of erysipelas the streptococci are found in large numbers in the lymphatics of the cutis and underlying tissues, just beyond the swollen margin of the inflammatory area. As the inflammation advances they gradually die out, and after a time their extension at the periphery comes to an end. The streptococci may extend to serous and synovial cavities and set up inflammatory or suppurative change,—peritonitis, meningitis, and synovitis may thus be produced.

Conjunctivitis.—A considerable number of organisms are concerned in the production of conjunctivitis and its associated lesions. Of these a number appear to be specially associated with this region. Thus a small organism, generally known as the Koch-Weeks bacillus, is the most common cause of acute

contagious conjunctivitis, especially prevalent in Egypt, but also common in this country. This organism is very minute, being little more than 1 μ in length, and morphologically resembles the influenza bacillus; its conditions of growth are even more restricted, as it rarely grows on blood agar, the best medium being serum agar. On this medium it produces minute transparent colonies like drops of dew. The obtaining of pure cultures is a matter of considerable difficulty, and it is nearly always accompanied by the xerosis bacillus. It can readily be found in the muco-purulent secretion by staining films with weak (1 : 10) carbol-fuchsin, and is often to be seen in the interior of leucocytes (Fig. 54). Another organism exceedingly like the previous, apparently differing from it only in the rather wider conditions of growth, is Müller's bacillus. It was cultivated by him in a considerable proportion of cases of trachoma, but its relation to this condition is still a matter of dispute. Another bacillus which is now well recognised is the diplo-bacillus of conjunctivitis first described by Morax. It is especially common in the more subacute cases of conjunctivitis. Eyre found it in 2·5 per cent. of all cases of conjunctivitis. Its cultural characters are given below. The xerosis bacillus, which is a small diphtheroid organism (Fig. 118), has been found in xerosis of the conjunctiva, in follicular conjunctivitis, and in other conditions; it appears to occur sometimes also in the normal conjunctiva. It is doubtful whether it has any pathogenic action of importance. Acute conjunctivitis is also produced by the pneumococcus, epidemics of the disease being sometimes due to this organism, and also by streptococci and staphylococci; the staph. albus may, however, often be found in the conjunctival sac when there is little or no evidence of inflammation. True diphtheria of the conjunctiva caused by the Klebs-Löffler bacillus also

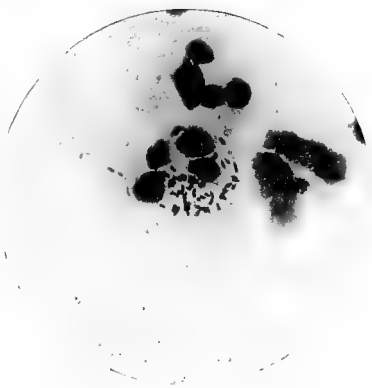

FIG. 54.—Film preparation from a case of acute conjunctivitis, showing Koch-Weeks bacilli, chiefly contained within a leucocyte. (From a preparation by Dr. Inglis Pollock.) ×1000.

occurs, whilst in gonorrhœal conjunctivitis, often of an acute purulent type, the gonococcus is present (p. 261).

Diplo-bacillus of Conjunctivitis.—This organism, discovered by Morax, is a small plump bacillus, measuring 1×2 μ, and usually occurring in pairs, or in short chains of pairs (Fig. 56). It is non-motile, does not form spores, and is decolorised by Gram's method. It does not grow on the ordinary gelatin and agar media, the addition of blood or serum being necessary. On serum it forms small rounded colonies which produce small pits of liquefaction; hence it has been

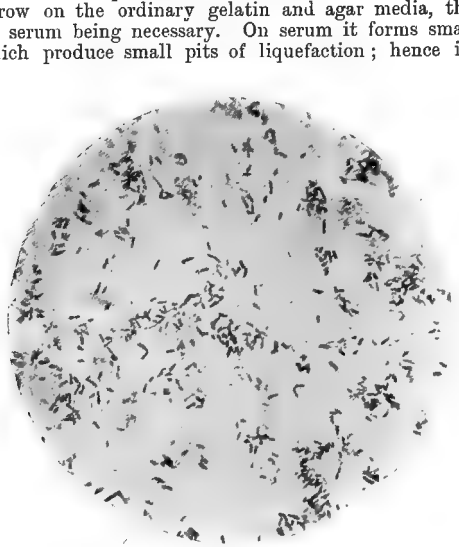

FIG. 55.—Koch-Weeks bacillus, from a young culture on blood agar. Stained with weak carbol-fuchsin. $\times 1000$.

called the *bacillus lacunatus*. In cultures it is distinctly pleomorphous, and involution forms also occur. It is non-pathogenic to the lower animals.

Acne.—In the pus of acne lesions and also in the comedones a bacillus of somewhat characteristic appearance may be found in large numbers. The organism was first described by Unna and afterwards cultivated by Sabouraud, and is now generally known as the *acne bacillus*. It occurs in the form of short rods, sometimes swollen at one end, and measuring about $1{\cdot}5$ μ in length and rather less than $\cdot 5$ μ in thickness. It stains readily with the basic aniline dyes and retains the stain in Gram's method. In cultures it grows best under anaerobic conditions, for example in deep tubes of 2 per cent. glucose agar, and the reaction of the

medium ought to be distinctly acid. In such a medium after three or four days' incubation at 37° C. small whitish colonies appear, which when examined under a low magnification are seen to have a lenticulate shape. The organism shows considerable pleomorphism,—coccoid, diphtheroid, and filamentous types being present, as well as irregular bizarre forms. Some observers have also obtained surface growth on ordinary agar, especially after the organism has been cultivated for some time under anaerobic conditions. Its relation to the suppuration in acne has been a matter of dispute, some holding that it is the cause of the suppuration, whilst others maintain that this is due to pyogenic cocci. There seems, however, to be little doubt that the bacillus is sometimes present alone.

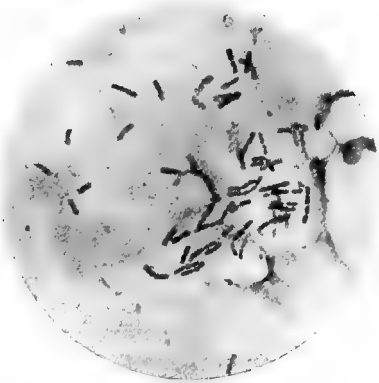

FIG. 56.—Film preparation of conjunctival secretion, showing the Morax diplo-bacillus of conjunctivitis. ×1000.

Acute Rheumatism.—There are many facts which point to the infective nature of this disease, and investigations from this point of view have yielded important results. Of the organisms isolated, the one which appears to have strongest claims is a small coccus observed by Triboulet, and by Westphal and Wassermann, the characters and action of which were first investigated in this country by Poynton and Paine. It is now usually known as the *micrococcus rheumaticus*. The organism is sometimes spoken of as a diplococcus, but it is best described as a streptococcus growing in short chains; in the tissues, however, it usually occurs in pairs. It is described as being rather smaller than the streptococcus pyogenes, and although it can be stained by Gram's method, it loses the colour more readily than the streptococcus pyogenes. In the various media it produces a large amount of acid, and usually clots milk after incubation for two days; on blood agar it alters the hæmoglobin to a brownish colour. Its growth on media generally is more luxuriant than that of the streptococcus, and it grows well on gelatin at 20° C. Injection of pure cultures in rabbits often produces polyarthritis

and synovitis, valvulitis and pericarditis, without any suppurative change—lesions which are not produced by the ordinary streptococci (Beattie). In one or two instances choreiform movements have been observed after injection. The organism is most easily obtained from the substance of inflamed synovial membrane where it is invading the tissues; a part where there is special congestion should be selected as being most likely to give positive results. It is only occasionally to be obtained from the fluid in joints. It has also been cultivated from the blood in rheumatic fever, from the vegetations on the heart valves, and from other acute lesions; in many cases, however, cultures from the blood give negative results. Beattie has shown that in rabbits the arthritis produced reproduces the main features of acute or subacute rheumatism in man, namely, the rapidity with which the affection passes from joint to joint, the tendency to relapses, the contributory effects of exposure to cold, and the absence of gross anatomical changes in the joints. Poynton and Paine cultivated the streptococcus from the cerebro-spinal fluid in three cases where chorea was present, and also detected it in the membranes of the brain. They consider that this disease is probably of the nature of a slight meningo-myelitis produced by the organism. The facts already accumulated speak strongly in favour of this organism being causally related to rheumatic fever, though this cannot be considered completely proved. Andrewes finds that the organism has the same cultural characters and fermentative effects as the streptococcus fæcalis, a common inhabitant of the intestine. Even, however, if the two organisms were the same, it might well be possible that rheumatic fever is due to an infection of the tissues by this variety of streptococcus. The clinical data, in fact, rather point to rheumatic fever being due to an infection by some organism frequently present in the body, brought about by some state of predisposition or acquired susceptibility. In view of the results recorded in some cases of "enterococcus" infection, with myalgia, etc., the question is again raised as to the identity of the organisms, and comparisons are clearly required. Beattie and Yates have brought forward important evidence to show that the joints do not become infected *post mortem* with the streptococci of the alimentary canal as a terminal phenomenon, and that accordingly the finding of the micrococcus rheumaticus in the joints has an important etiological significance.

Vaccination Treatment of Infections by the Pyogenic Cocci.—From his study of the part played by phagocytosis in the

successful combat of the pyogenic bacteria by the body, Wright was led to advocate the treatment of such infections during their course by active immunisation by means of dead cultures of the infecting agent (for methods of preparation, see p. 130). The treatment is applicable when the infection is practically local, as in acne pustules, in boils, etc., but has also been applied in more acute conditions. (For the theoretical questions raised, see Immunity.) For an isolated furuncle, Wright recommends a dose of 50 to 100 million staphylococci to be followed three or four days later by the injection of 250 to 300 millions, and for an incipient streptococcic lymphangitis a dose of 500,000 to 2,000,000 streptococci. In chronic staphylococcal infections the number of bacteria used for an injection is from 250,000,000 to 500,000,000, but a smaller number may give a good result, and the general principle to be adopted is to use the smallest dose necessary for a therapeutic effect. If it is not practicable to use the strain derived from the lesion for the preparation of an "autogenous" vaccine, then laboratory cultures or the stock vaccines which are now in the market may be used; in such cases it is well to use a "polyvalent" vaccine made from a mixture of strains; in skin infections a mixture of staphylococcus aureus and albus may be employed. The treatment of various staphylococcus infections, such as pustular acne, boils, and chronic abscesses, by vaccines, has been carried out very extensively, in many cases with good result, and a similar statement is true of some streptococcic infections. Vaccine therapy has also been used in inflammatory and suppurative conditions due to other organisms, for example, infections of the genito-urinary tract with b. coli, where an autogenous vaccine with initial doses of from 10,000,000 to 50,000,000 may be employed; gonococcal arthritis, where the initial dose is from 1,000,000 to 5,000,000 organisms; chronic respiratory catarrh. The case of the last can usually only be met by mixed vaccines on account of the presence of different species of bacteria, several of which may be potentially pathogenic; in these circumstances the use of a mixed vaccine is purely empirical.

The treatment has also been applied in acute streptococcic infections, *e.g.*, with the pyogenic cocci, b. coli, etc., very small doses—*e.g.*, from 200,000 to 5,000,000 being given—but the method has not been attended by striking success. It is stated that better results have been obtained by the use of sensitised vaccines (*q.v.*), very small doses being here again employed.

Methods of Examination in Inflammatory and Suppurative Conditions.—These are usually of a comparatively simple nature,

and include (1) microscopic examination, (2) the making of cultures.

(1) The pus or other fluids should be examined microscopically, first of all by means of film preparations in order to determine the characters of the organisms present. The films should be stained (*a*) by one of the ordinary solutions, such as carbol-thionin-blue (p. 102), or a saturated watery solution of methylene-blue; and (*b*) by Gram's method. The use of the latter is of course of high importance as an aid in the recognition.

(2) The cultivation and separation of the organisms from the lesions are best attained by the method of successive strokes on agar plates or on agar tubes, the former being preferable (p. 58). In the case of an organism requiring a special medium, this of course is to be used. Inoculation experiments may be carried out as occasion arises.

In cases of suspected blood infection the examination of the blood is to be carried out by the methods already described (p. 70).

CHAPTER VIII.

INFLAMMATORY AND SUPPURATIVE CONDITIONS, *CONTINUED:* THE ACUTE PNEUMONIAS, EPIDEMIC CEREBRO-SPINAL MENINGITIS.

Introductory.—The term Pneumonia is applied to several conditions which present differences in pathological anatomy and in origin. All of these, however, must be looked on as varieties of inflammation in which the process is modified in different ways, depending on the special structure of the lung or of the parts which compose it. There is, first of all—and, in adults, the commonest type—the acute croupous or lobular pneumonia, in which an inflammatory process attended by abundant fibrinous exudation affects, by continuity, the entire tissue of a lobe or of a large portion of the lung. It departs from the course of an ordinary inflammation in that the reaction of the connective tissue of the lung is relatively slight, and there is usually no tendency for organisation of the inflammatory exudation to take place. Secondly, there is the acute catarrhal or lobular pneumonia, where a catarrhal inflammatory process spreads from the capillary bronchi to the air vesicles, and in these, changes, consisting on the one hand of capillary bronchitis with aspiration of the exudate into the alveoli and on the other of proliferation of the endothelium of the alveoli, take place which lead to consolidation of patches of the lung tissue. Up till 1889 acute catarrhal pneumonia was comparatively rare except in children. In adults it was chiefly found as a secondary complication to some condition such as diphtheria, typhoid fever, etc. Since, however, influenza in an epidemic form has become frequent, catarrhal pneumonia has been of much more common occurrence in adults, has assumed a very fatal tendency, and has presented the formerly quite unusual feature of being sometimes the precursor of gangrene of the lung. Besides these two definite types other forms also exist. Thus instead of a fibrinous material the exudation may be of a serous, hæmorrhagic, or purulent char-

acter. Cases of mixed fibrinous and catarrhal pneumonia also occur, and in the catarrhal there may be great leucocytic emigration. Hæmorrhages may also be observed.

Besides the two chief types of pneumonia there is another group of cases which are somewhat loosely denominated septic pneumonias, and which may arise in two ways: (1) by the entrance into the trachea and bronchi of discharges, blood, etc., which form a nidus for the growth of septic organisms—these often set up a purulent capillary bronchitis and lead to infection of the air cells and also of the interstitial tissue of the lung; (2) from secondary pyogenic infection by means of the blood stream from suppurative foci in other parts of the body. (See chapter on Suppuration, etc.) In these septic pneumonias various changes, resembling those found in the other types, are often seen round the septic foci.

In pneumonias, therefore, there may be present a great variety of types of inflammatory reaction. We shall see that with all of them bacteria have been found associated. Special importance is attached to acute croupous pneumonia on account of its course and characters, but reference will also be made to the other forms.

Historical.—Acute lobar pneumonia for long was supposed to be an effect of exposure to cold; but not only did cases occur where no such exposure could be traced, but it had been observed that the disease sometimes occurred epidemically, and was occasionally contracted by hospital patients lying in beds adjacent to those occupied by pneumonia cases. Further, the sudden onset and definite course of the disease conformed to the type of an acute infective fever; it was thus suspected by some to be due to a specific infection. This view of its etiology was promulgated in 1882–83 by Friedländer, who observed in the lungs capsulated cocci, which he isolated and showed to possess pathogenic properties. The situation was complicated by the subsequent observation that the injection into animals of the sputum of healthy individuals frequently originated a septicæmic condition with the presence of capsulated cocci in the blood. The significance of the occurrence of this "sputum septicæmia" could not at that period be properly realised, as it was not recognised that an organism could produce different results in different animals, and therefore it was thought that the organisms described by Friedländer were not specifically related to pneumonia. Somewhat later, A. Fraenkel described diplococci in pneumonia which differed culturally from those of Friedländer. The work of Weichselbaum in 1886 elucidated the subject further. This observer, investigating 129 cases of various types of pneumonia, isolated, first and most frequently, an organism he denominated the *diplococcus pneumoniæ* (with a variant named by him the *streptococcus pneumoniæ*), which corresponded to Fraenkel's organism; second, an organism he described as the *bacillus pneumoniæ*, occurring less frequently and which corresponded with that originally noted by Friedländer.

Under certain circumstances other organisms, notably the b. pestis, have been found to originate pneumonic processes.

The general result of all observations on pneumonia has been to establish that the organism described by Fraenkel and now known as the *pneumococcus*, is that of most frequent occurrence; it is the sole organism present in about 95 per cent. of cases of lobar pneumonia.

Microscopic Characters of the Pneumococcus.—*Methods.*—The organisms present in acute pneumonia can best be examined in film preparations made from pneumonic lung (preferably from a part in a stage of acute congestion or early hepatisation), or from the gelatinous parts of pneumonic sputum (here again preferably when such sputum is either rusty or occurs early in the disease), or in sections of pneumonic lung. Such preparations are best stained by Gram's method, with Bismarck-brown or Ziehl-Neelsen carbol-fuchsin (one part to thirty of water) as a contrast stain; with the latter it is best either to stain for only a few seconds, or to overstain and then decolorise with alcohol till the ground of the preparation is just tinted; in this way the capsules can often be demonstrated. The capsules can also be stained by the methods already described (p. 107). In such preparations as the above, and even in specimens taken from the lungs immediately after death (as may be quite well done by means of a hypodermic syringe), putrefactive and other bacteria may be present. Similar methods are applicable to the numerous other lesions besides pneumonia in which the pneumococcus occurs.

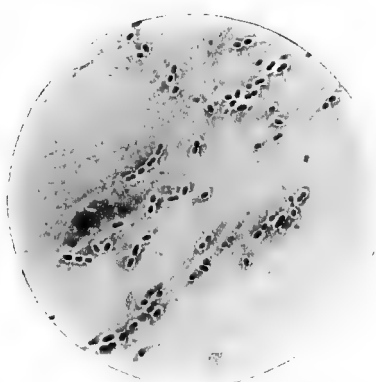

FIG. 57.—Film preparations of pneumonic sputum, showing numerous pneumococci (Fraenkel's) with unstained capsules; some are arranged in short chains. See also Plate I., Fig. 2.
Stained with carbol-fuchsin. ×1000.

The pneumococcus occurs in the form of a small oval coccus, about 1 μ in longest diameter, arranged generally in pairs (diplococci), but also in chains of four to ten (Fig. 57). The free ends are often pointed like a lancet, hence the term *diplococcus lanceolatus* has also been applied to it. These cocci, in their typical form, have round them a capsule, which, in films stained by ordinary methods, usually appears as an

unstained halo, but is sometimes stained more deeply than the ground of the preparation. This difference in staining depends, in part at least, on the amount of decolorisation to which the preparation has been subjected. The capsule is rather broader than the body of the coccus, and has a sharply defined external margin. The organism takes up the basic aniline stains with great readiness and also *retains the stain in Gram's method.* In any lesion many dead individuals often occur, and these may be obviously degenerated and may lose their Gram-positive character.

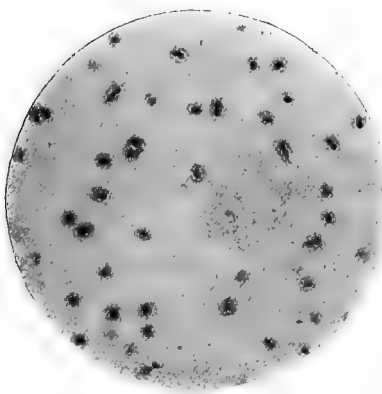

FIG. 58.—Fraenkel's pneumococcus in serous exudation at site of inoculation in a rabbit, showing capsules stained. Stained by Rd. Muir's method. ×1000.

In sputum preparations the capsule of the pneumococcus may not be recognisable, and the same is sometimes true of lung preparations and of pneumococcal exudates in other parts of the body. Sometimes in preparations stained by ordinary methods the difficulty of recognising the capsule when it is present is due to the refractive index of the fluid in which the specimen is mounted being almost identical with that of the capsule. This difficulty can be overcome by having the groundwork of the preparation tinted.

The Cultivation of the Pneumococcus.—It is often difficult, and sometimes impossible, to isolate this coccus directly from pneumonic sputum. On culture media it has not a vigorous growth, and when mixed with other bacteria it is apt to be overgrown by the latter. To get a pure culture it is best to insert a small piece of the sputum beneath the skin of a rabbit or a mouse. In about twenty-four to forty-eight hours the animal will die, with numerous capsulated pneumococci throughout its blood. From the heart-blood cultures can be easily obtained. Cultures can also be got *post mortem* from the lungs of pneumonic patients by streaking a number of agar or blood-agar tubes with a scraping taken from the area of acute congestion or commencing red hepatisation, and incubating them at

37° C. This method is also sometimes successful in the case of sputum.

The appearances presented in cultures by different varieties of the pneumococcus vary somewhat. It always grows best on blood serum or on Pfeiffer's blood agar. It often grows well on ordinary agar or in bouillon, but not so well on glycerin agar. In a stroke culture on *blood serum* growth appears as an almost transparent pellicle along the track, with isolated colonies at the margin. On *agar* media it is more manifest, but otherwise has similar characters. On agar plates colonies are very transparent, but under a low power of the microscope appear to have a compact finely granular centre and a pale transparent periphery; after forty-eight hours they increase slightly in size and present a depressed centre (Fig. 59). The appearances are similar to those of a culture of streptococcus pyogenes, but the growth is less vigorous, and is more delicate in appearance. A similar statement also applies to cultures in *gelatin* at 22° C., growth in a stab culture appearing as a row of minute points which remain of small size; there is no liquefaction of the medium. In *bouillon* (which must be made from fresh meat—rabbit muscle being suitable) growth forms a slight turbidity, which settles to the bottom of the vessel as a dust-like deposit. On *potato*, as a rule, no growth appears. Cultures may be maintained for long periods, if fresh sub-cultures are made every four or five days, but they tend ultimately to die out. They sometimes rapidly lose their virulence, so that four or five days after isolation from an animal's body their pathogenic action disappears, but this is not always the case, especially if serum bouillon be used for maintaining sub-cultures; virulence may also be maintained by the whole blood of an infected rabbit even when this is almost dried up, or in the spleen of an infected mouse kept dry *in vacuo*. In ordinary artificial media pneumococci usually appear as diplococci without a capsule, but in preparations made from the surface of agar or from bouillon, shorter or longer chains may be observed (Fig. 60). After a few days' growth they lose their regular shape and size, and

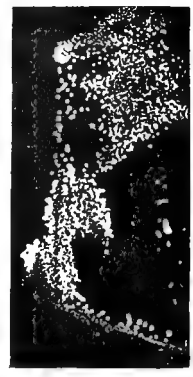

FIG. 59.—Stroke culture of Fraenkel's pneumococcus on blood agar. The colonies are large and unusually distinct. Twenty-four hours' growth at 37° C. Natural size.

involution forms appear, usually in the form of pointed rods due to elongation of a coccus without division. Usually the pneumococcus does not grow below 22° C., but forms in which the virulence has disappeared often grow well at 20° C. Its optimum temperature is 37° C., its maximum 42° C. It is preferably an aerobe, but can exist without oxygen. It prefers a slightly alkaline medium to a neutral, and does not grow on an acid medium. In ordinary media, as just stated, the pneumococcus does not usually appear to develop a capsule, but, according to Hiss, the absence of a capsule is often only apparent, and if in making cover-glass preparations off such media some serum be used as the diluent, and the films stained be by his copper-sulphate method (p. 107), a capsule can be demonstrated. Capsulation frequently appears in fluid serum media, *e.g.*, if the organism be grown in rabbit or human serum which has been obtained under aseptic precautions and heated for half an hour at 55° C. or on agar slopes over which a drop of serum has been run.

FIG. 60.—Fraenkel's pneumococcus from a pure culture on blood agar of twenty-four hours' growth, some in pairs, some in short chains. Stained with weak carbol-fuchsin. ×1000.

The pneumococcus is non-hæmolytic on blood-agar plates (p. 45), and it ferments saccharose, raffinose, and lactose; a similar fermentative action on inulin is important, as ordinary streptococci do not ferment this sugar. Apparently some samples of inulin are more readily acted on than others. Usually the test is carried out with Hiss's inulin serum water medium, in which coagulation of the serum results (p. 46), but some investigators have had more success with inulin bouillon, acid production being estimated by titration against soda with a phenolphthalein indicator.

The pneumococcus is soluble in bile. To demonstrate this, fresh ox bile autoclaved for twenty minutes at 120° C. and filtered is added to a fully developed fluid culture (which must be one in simple bouillon) in the proportion of about a fifth of the

culture. Two per cent sodium taurocholate may be similarly used.

The facts that in cultures the pneumococcus often grows in chains, and that occasionally streptococci are found to develop capsules, have raised the question of the relationship of the pneumococcus to other streptococci. In determining the true pneumococci, biological as well as morphological characters must be studied, and here the bile solubility of the pneumococcus, its failure to produce hæmolysis, and its capacity of fermenting inulin are the important characters. It must be stated, however, as bearing on the close relationships of the pneumococci and streptococci, that Rosenau believes he has succeeded in transforming streptococci into capsulated organisms having all these biological features of the pneumococcus.

Considerable attention has been directed to a group of cocci originally described by Schottmüller, isolated from various disease conditions in man (pneumonia, meningitis, suppurations), which besides possessing voluminous capsules have these surrounded by a viscous material which gives a slimy consistence to cultures and also to pathological exudates. These are related to the pneumococci on the one hand and to the streptococci on the other. The work of the Rockefeller investigators (*v. infra*) suggests that these organisms ought to be classified into two groups. (1) The *pneumococcus mucosus*. This organism tends to be not so pointed as the ordinary pneumococcus, and its colonies are larger; it is non-hæmolytic on blood agar, soluble in bile, gives rise to acid and clot in Hiss's inulin serum-water, and is very pathogenic to white mice and rabbits. Anti-sera produced by strains of this coccus, while showing cross agglutination towards members of their own group, do not agglutinate streptococci and usually also not other pneumococci. (2) The *streptococcus mucosus*. This organism is generally round, occurs in chains, and the colonies are less transparent than those of the pneumococcus; it is usually non-hæmolytic, is not soluble in bile, does not ferment inulin, and is less pathogenic to mice than the last. Thus while the pneumococcus mucosus is practically a true pneumococcus, the streptococcus mucosus forms a connecting link with the true streptococci.

The Occurrence of the Pneumococcus in Pneumonia and other Conditions.—The pneumococcus occurs in every variety of the disease—in acute croupous pneumonia, in broncho-pneumonia, in septic pneumonia. In a case of croupous pneumonia the pneumococci are found all through the affected area in the lung, especially in the exudation in the air-cells. They

also occur in the pleural exudation and effusion, and in the lymphatics of the lung. The greatest number are found in the parts where the inflammatory process is most recent, *e.g.*, in an area of acute congestion in a case of croupous pneumonia, and therefore such parts are preferably to be selected for microscopic examination, and as the source of cultures. When the inflammation is resolving, some of the organisms often stain badly (*e.g.*, tend to lose the Gram-positive reaction); such individuals are probably either dead or dying. Sometimes there occur in pneumonic consolidation areas of suppurative softening, which may spread diffusely. In such areas the pneumococci occur with or without ordinary pyogenic organisms, streptococci being the commonest concomitants. In other cases, especially when the condition is secondary to influenza, gangrene may supervene and lead to destruction of large portions of the lung. In these a great variety of bacteria, both aerobes and anaerobes, are to be found.

In ordinary broncho-pneumonias also Fraenkel's pneumococcus is usually present, sometimes along with pyogenic cocci; in the broncho-pneumonias secondary to diphtheria it may be accompanied by the diphtheria bacillus, and also by pyogenic cocci; in typhoid pneumonias the typhoid bacilli or the b. coli may be alone present or be accompanied by the pneumococcus, and in influenza pneumonias the influenza bacillus may occur. In septic pneumonias the pyogenic cocci in many cases are the only organisms discoverable, but the pneumococcus may also be present. Especially important, as we shall see, from the point of view of the etiology of the disease, is the occurrence in other parts of the body of pathological conditions associated with the presence of the pneumococcus. By direct extension to neighbouring parts, empyema, pericarditis, and lymphatic enlargements in the mediastinum and neck may take place; in the first the pneumococcus may occur either alone or with pyogenic cocci. But distant parts may be affected, and the pneumococcus may be found in suppurations and inflammations in various parts of the body (subcutaneous tissue, peritoneum (especially in children), joints, kidneys, liver, etc.), in otitis media, ulcerative endocarditis (p. 217), and meningitis. In fact, there is practically no inflammatory or suppurative condition in the body in which the pneumococcus in pure culture may not be found. These conditions may take place either as complications of pneumonia, or they may constitute the primary disease. The occurrence of meningitis is of special importance, for next to the lungs the meninges appear to be the parts most liable to attack by the

pneumococcus. A large number of cases have been investigated by Netter, who gives the following tables of the relative frequency of the primary infections by the pneumococcus in man :—

(1) In adults—

Pneumonia	65·95 per cent.
Broncho-pneumonia / Capillary bronchitis	15·85 ,,
Meningitis	13·00 ,,
Empyema	8·53 ,,
Otitis	2·44 ,,
Endocarditis	1·22 ,,
Liver abscess	1·22 ,,

(2) In children 46 cases were investigated. In 29 the primary affection was otitis media, in 12 broncho-pneumonia, in 2 meningitis, in 1 pneumonia, in 1 pleurisy, in 1 pericarditis.

Thus in children the primary source of infection is in a great many cases an otitis media, and Netter concludes that infection takes place in such conditions from the nasal cavities.

As bearing on the occurrence of pneumococcal infections secondary to such a local lesion as pneumonia, it is important to note that in a large proportion of cases of the latter disease the pneumococcus can be isolated from the blood.

Experimental Inoculation.—The *pneumococcus* of Fraenkel is pathogenic to various animals, though the effects vary somewhat with the virulence of the race used. The susceptibility of different species, as Gamaleia has shown, varies to a considerable extent. The rabbit, and especially the mouse, are very susceptible; the guinea-pig, the rat, the dog, and the sheep occupy an intermediate position; the pigeon is immune. In the more susceptible animals the general type of the disease produced is not pneumonia, but a general *septicæmia*. Thus, if a rabbit or a mouse be injected subcutaneously with pneumonic sputum, or with a scraping from a pneumonic lung, death occurs in from twenty-four to forty-eight hours. There is some fibrinous infiltration at the point of inoculation, the spleen is often enlarged and firm, and the blood contains capsulated pneumococci in large numbers (Fig. 61). If the seat of inoculation be in the lung, there generally results pleuritic effusion on both sides, and in the lung there may be a process somewhat resembling the early stage of acute croupous pneumonia in man. There are often also pericarditis and enlargement of spleen. We have already stated that cultures of the pneumococcus on artificial media may lose their virulence. Now, if such a partly attenuated culture be injected subcutaneously into a rabbit, there is greater local reaction; pneumonia, with exudation of lymph

on the surface of the pleura, and a similar condition in the peritoneum, may occur. It may also be said that if a rabbit be immunised with dead or attenuated cultures and then injected with a virulent culture, similar local reactions may occur at the inoculation site. In sheep greater immunity is marked by the occurrence, after subcutaneous inoculation, of an enormous local sero-fibrinous exudation, and by the fact that few pneumococci

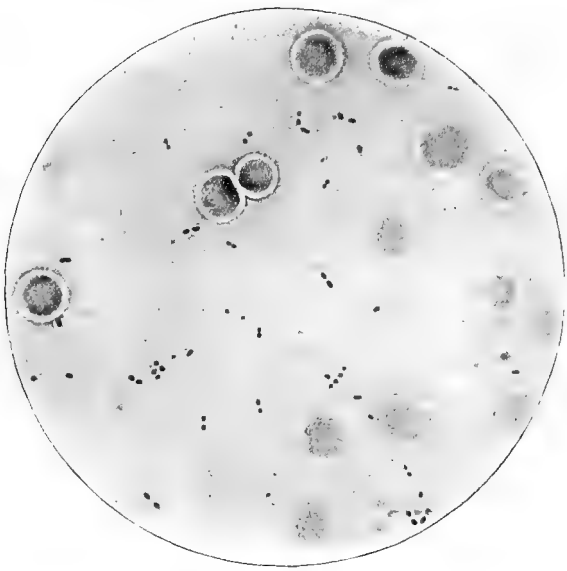

FIG. 61.—Capsulated pneumococcus in blood taken from the heart of a rabbit, dead after inoculation with pneumonic sputum.
Dried film, fixed with corrosive sublimate. Stained with carbol-fuchsin and partly decolorised. ×1000.

are found in the blood stream. Intra-pulmonary injection in sheep is followed by a typical pneumonia, which is generally fatal. The dog is still more immune; in it also intra-pulmonary injection is followed by a fibrinous pneumonia, which is only sometimes fatal. Inoculation by inhalation appears only to have been performed in the susceptible mouse and rabbit; here also septicæmia resulted. By intra-tracheal inoculation in dogs Lamar and Meltzer have produced a fibrinous pneumonia pathologically similar to what occurs in man.

The general conclusion to be drawn from these experiments thus is that in highly susceptible animals virulent pneumococci produce a general septicæmia; whereas in more immune species there is an acute local reaction at the point of inoculation, and if the latter be in the lung, then there may result pneumonia, which, of course, is merely a local acute inflammation occurring in a special tissue, but identical in essential pathology with an inflammatory reaction in any other part of the body. When a dose of pneumococci sufficient to kill a rabbit is injected subcutaneously in the human subject, it gives rise to a local inflammatory swelling with redness and slight rise of temperature, all of which pass off in a few days. It is therefore justifiable to suppose that man occupies an intermediate place in the scale of susceptibility, probably between the dog and the sheep, and that when the pneumococcus gains an entrance to his lungs the local reaction in the form of pneumonia occurs. In this connection the occurrence of manifestations of general infection associated with pneumonia in man is of the highest importance. We have seen that meningitis and other inflammations are not very rare complications of the disease, and such cases form a link connecting the local disease in the human subject with the general septicæmic processes which may be produced artificially in the more susceptible representatives of the lower animals.

A fact which at first appeared rather to militate against the pneumococcus being the cause of pneumonia was the discovery by Pasteur and others of this organism in the saliva of healthy men. It can certainly be isolated by inoculation of susceptible animals, from the mouths of a considerable proportion of normal men, from their nasal cavities, etc., being probably in any particular individual more numerous at some times (especially, it is stated, during the winter months, *i.e.*, a little before the period of the greatest prevalence of pneumonia) than at others, and sometimes being entirely absent. This may indicate the importance of predisposing causes in the etiology of the disease, which applies in the case of the diseases caused by pyogenic staphylococci, streptococci, the bacillus coli, etc. By such causes the vitality and power of resistance of the lung may be diminished, and then the pneumococcus gain an entrance. We can therefore understand how less definite devitalising agents such as cold, alcoholic excess, etc., can play an important part in the causation of pneumonia. In this way also other abnormal conditions of the respiratory tract,—a slight bronchitis,—etc., may play a similar part. It must be stated, however, that according to the Rockefeller investigations (*infra*) the pneumo-

coccus occurring in the healthy naso-pharynx is usually of Type IV., *i.e.*, belongs to the group least pathogenic to man. The more pathogenic types are found almost exclusively in the mouths of convalescents and of contacts and in rooms where pneumonia cases have been nursed. While these types usually rapidly disappear from convalescents and contacts they may persist long enough to justify the view that certain persons may act as carriers of the disease.

It is more difficult to explain why sometimes the pneumococcus is associated with a spreading inflammation, as in croupous pneumonia, whilst at other times it is localised to the catarrhal patches in broncho-pneumonia. It is quite likely that in the former condition the organism is possessed of a different order of virulence, though of this we have no direct proof. We have, however, a closely analogous fact in the case of erysipelas; this disease, we have stated reasons for believing, is produced by a streptococcus which, when less virulent, causes only local inflammatory and suppurative conditions.

Summary.—We may accordingly summarise the facts regarding the relation of Fraenkel's pneumococcus to the disease by saying that it can be isolated from nearly all cases of acute croupous pneumonia, and also from a considerable proportion of other forms of pneumonia. When injected into the lungs of moderately insusceptible animals it gives rise to pneumonia. We are therefore justified in holding that it is the chief factor in causing croupous pneumonia, and also plays an important part in other forms.

Immunisation against the Pneumococcus.—Animals can be immunised against the pneumococcus by inoculation with virulent cultures killed by heating at 55° C., with cultures which have become attenuated by growth on artificial media, or with the naturally attenuated cocci which occur under various circumstances. Sometimes one or two injections, at intervals of several days, are sufficient for immunisation, but the immunity has been observed to be usually of a fleeting character and may not last more than a few weeks; a process of intensive and rapid immunisation is described below. The serum of such immunised animals mixed *in vitro* with pneumococci neutralises the action of these in susceptible animals, may also protect against subsequent inoculation with carefully regulated doses of pneumococci, and if injected within twenty-four hours after inoculation, may prevent death. Such serum also possesses an agglutinating action in low dilutions on the pneumococcus originating the immunity.

Differentiation of Strains of the Pneumococcus by Antisera.—The possibility of effecting this is one of the most important consequences of the study of immunity against the pneumococcus. It had been long recognised that strains of the pneumococcus derived from different sources present individual peculiarities, but it was not till the recent exhaustive investigation of the subject in the Rockefeller Institute, New York, that definite results were obtained. In the study of the agglutinating and protecting properties of antisera prepared by inoculating animals against a long series of cultures isolated from cases of acute lobar pneumonia, it was proved that sera derived from certain strains, on the one hand, would almost indiscriminately agglutinate some of these strains, and, on the other, had little or no effect on other strains. It was further found that the agglutinating and protective qualities of these sera were parallel. In this way it was possible to group the strains under four types. Three of them (I., II., III.) were definite, and a fourth (IV.) was formed of strains in which an antiserum usually only agglutinated the strain which originated it, and had little or no capacity of agglutinating the strains of Types I., II., III. The members of Type III. could be recognised not only by their originating agglutinating sera specific to the group, but presented cultural features which characterised them as the *pneumococcus mucosus* (see p. 231). Types I. and II. between them accounted for 60 per cent. of the cases of pneumonia studied and are of relatively high virulence for man, this being specially the case with Type II. Type III., while accounting for only 12 per cent. of cases, is of highest virulence, the mortality with it being 45 per cent. Type IV. was found in 24 per cent. of cases and caused the lowest mortality (16 per cent.); the strains occurring in the mouth of healthy individuals probably belong to this type. The fundamental facts of the New York investigation have been confirmed by observers elsewhere, and are obviously of great practical importance for diagnosis and, as we shall see, for treatment. It is probable, however, that in different parts of the world different strains prevail. Thus, in South Africa, Lister has found that, while the New York Types I. and II. are common, nearly a third of all cases of pneumonia are associated with another type which apparently does not occur to any extent in New York.

Methods of classifying Pneumococci by Agglutination.—This depends on the observer being furnished with the type sera (I., II., III.) of the Rockefeller Institute. A white mouse is inoculated intraperitoneally with 0·5 to 1 c.c. of a saline emulsion of a bean-sized piece of sputum,

freed of surface contamination by washing in sterile saline. The mouse may die in from five to twenty-four hours, and if the peritoneal exudate contains a strong and fairly pure growth of the pneumococcus the abdominal cavity is washed out with 5 c.c. saline, cultures being at the same time made in broth and on blood-agar plates. The peritoneal washings are first centrifuged slowly to precipitate gross material, and the supernatant fluid is then centrifuged at a high speed to precipitate the bacteria. The bacterial deposit is emulsified in saline to form a fairly heavy suspension which is used for a macroscopic sedimentation test. If the pneumococci in blood cultures or in other exudates are to be employed, emulsions may be obtained by similar procedures. A bacterial emulsion being prepared, 0·5 c.c. of Serum I. (1–20), 0·5 c.c. of Serum II. (undiluted), 0·5 c.c. of Serum II. (1–20), and 0·5 c.c. of Serum III.[1] (1–5) are placed in four tubes, and 0·5 c.c. bacterial emulsion added to each, and in a fifth tube a mixture of 0·1 c.c. sterile ox bile and 0·4 c.c. bacterial emulsion is made up; the series is placed in a water bath at 37° C. for one hour, and the result read off. Sedimentation in any one of the four tubes indicates that the strain belongs to the type by the serum of which it is agglutinated: if no reaction occurs in any of the tubes, and the organism is soluble in bile, it belongs to Type IV.

The Treatment of Pneumonia with Anti-sera.—Many years ago the Klemperers treated a certain number of cases of human pneumonia by serum derived from immune animals, apparently with a certain measure of success, and more recently Römer issued through Merck a polyvalent serum prepared by immunising different species of animals with growths of the pneumococcus on sheep-serum glycerine bouillon and mixing their sera. The results obtained, though in some cases satisfactory, were irregular, and the subject was illuminated by Neufeld and Haendel, who insisted that in the use of any anti-pneumococcic serum means should be taken for ensuring that it had an antagonistic action on the particular strain present in the particular infection treated.

Evidence confirming this view has been obtained in the New York investigations on pneumonia, in which the determination of the different types of the pneumococcus was followed by an estimate of the therapeutic capacities of the anti-sera prepared against Types I., II., III. (*v. supra*). It was found that while the anti-serum to Type I. had a marked curative effect on cases of pneumonia due to the Type I. pneumococcus, the anti-sera to Types II. and III. had practically no effect on cases attributable to these types; furthermore the anti-serum to Type I. had little or no effect on cases caused by Types II. and III. These facts throw light on the irregular and generally disappointing result obtained hitherto with the ordinary polyvalent antipneumococcal

[1] There is apparently sometimes difficulty in effecting the agglutination of Type III. on account of the consistence of its capsule, and special methods may be necessary; see Hanes, *Journ. Exp. Med.*, 1914, xix. 38.

sera. The Rockefeller serum is prepared by immunising horses first with dead cultures; daily injections are given for six days, followed by an interval of a week, then six further daily injections are given; it is sometimes necessary to follow these up by the use of living organisms. Uniformity of strength in successive sera thus prepared is secured by determining the largest amount of an eighteen hours' culture against which 0·2 c.c. of the serum will protect a white mouse,—a comparison with the effects of the same amount of a standard serum being at the same time made. In the therapeutic application of the serum in a case of Type I. pneumonia large quantities must be used, and it is therefore a necessary preliminary to determine whether the patient exhibits hypersensitiveness to horse serum, and to desensitise him if this exists (see chapter on Immunity). If the way be clear, the serum, diluted with an equal amount of sterile saline made with freshly distilled water, is administered by the intravenous method—10–15 c.c. being given at the rate of 1 c.c. per minute —changes in the heart's action and in respiration and the occurrence of urticaria being watched for, and the treatment being suspended for a quarter of an hour if untoward symptoms seem to increase; if this does not occur, the remainder of the first dose may be given during fifteen minutes. The initial dose should be from 90–100 c.c., and the injections ought to be repeated every eight hours till about 250 c.c. serum have been given. Very soon after commencement of treatment the temperature may rise, but this is quickly succeeded by a fall, with improvement in the patient's general condition, stoppage of extension of the lung lesion, and prevention of invasion of the blood by the pneumococci. The effects of the treatment so far have been satisfactory,—of 107 cases treated in the Rockefeller Institute Hospital up to October 1917 only 7·5 per cent. died, as compared with a mortality of 25 to 30 per cent. in cases of Type I. pneumonia before the serum treatment was introduced. Up to the present no means of treating pneumonia of Types II. and III. by serum methods have been found practicable, and, as has been stated, the pneumococci of Type IV. do not yield a group anti-serum.

The Pathology of Pneumococcus Infection.—The effects of the action of the pneumococcus, at any rate in a relatively insusceptible animal such as man, seem to indicate that toxins may play an important part. Pneumonia is a focal disease which presents at the same time the character of an acute poisoning. In very few cases does death take place from the functions of the lungs being interfered with to such an extent as to cause asphyxia. It is from cardiac failure, from grave

interference with the heat-regulating mechanism, and from general nervous depression that death usually results. These considerations, taken in connection with the fact that in man the organisms are found in the greatest numbers in the lung, suggest that a toxic action is at work. Various attempts have been made to isolate toxins having specific effects, but these have been unsuccessful. The general conclusion has been that the toxins at work in pneumonia are intracellular; as in other cases, we may have to reckon with the distribution in the infected body of poisonous substances consequent on lysis of the infective agent. While the chief multiplication of the pneumococcus in pneumonia occurs in the lung, the organism frequently is found in the blood, and according to some observers its presence in greater numbers than 15 cocci per c.c. is of fatal import.

There has been considerable difference of opinion as to the explanations to be given of the facts observed regarding immunisation against the pneumococcus, and especially regarding the protective and curative properties of immune sera. There is no evidence that such sera possess either antitoxic or bactericidal properties. Within recent times many have accordingly turned to the opsonic property of sera to account for the facts observed. In this connection Mennes observed that normal leucocytes only become phagocytic towards pneumococci when they are lying in the serum of an animal immunised against this bacterium. Wright instanced the pneumococcus as an organism insensible to bactericidal action but very sensitive to opsonins, and Neufeld and Rimpau have described the occurrence of an opsonic—or, as they called it, a bacteriotropic—effect in the action of an anti-pneumococcic serum.

In studying further the relationship of the opsonic effect to pneumococcic infection, inquiry has been directed to the opsonic qualities of the blood of pneumonic patients, especially with a view to throwing light on the nature of the febrile crisis, the essential nature of which is, however, still entirely obscure. According to some results, the opsonic index as compared with that of a healthy person is not above normal, but if the possible phagocytic capacities of the whole blood of the sick person be taken into account, these may be above normal in consequence of the leucocytosis which usually accompanies a successful resistance to this infection. It has been observed, however, that as the crisis approaches in a case which is to recover, the opsonic index rises, and after defervescence gradually falls to normal. Correlated with this, there has been observed about the crisis an increase in the serum of substances capable of

protecting animals against pneumococcal infection. These must at present be looked on as the bodies concerned in the curative action of anti-serum. With regard to them Neufeld and Haendel insist that the concentration in the patient's blood, rather than the amount present in the body, is the important factor. There is experimental evidence that when the concentration is above a certain degree an enormous number of pneumococci can be successfully disposed of, while with a concentration below this limit a relatively small dose may prove fatal. As bearing on the factors involved in the successful resistance of the organism to the pneumococcus, it has been noted that avirulent pneumococci are more readily opsonised than more virulent strains. It is further stated that avirulent cultures of the pneumococcus can be made to resist phagocytosis if they are treated with the products of the autolysis of virulent strains or with washings from such strains, and that virulent cocci if washed with saline become capable of being readily phagocyted. While it cannot be stated definitely that the opsonic qualities of the serum are the essential factors in resistance to the pneumococcus, it is probable that the activities of the leucocytes play a part in the process. It has long been known that a leucocytosis occurs in the disease, and the degree of this is related to the outlook in the case. Thus, a low leucocyte count when correlated with the clinical symptoms indicates either a mild infection or a grave condition in which resistance is deficient. A count of over 10,000 per c.mm., progressively increasing, is a favourable sign in an uncomplicated pneumonia. The part played by the leucocytes has also been investigated experimentally by rendering the bone-marrow aplastic by means of benzol; under such circumstances the resistance of the animal to infection is diminished (Winternitz and Kline).

A substance derived from the infecting pneumococcus sometimes appears in the urine during pneumonia. It gives a precipitin reaction with the anti-serum corresponding to the type of pneumococcus causing the infection, and can be detected by mixing equal quantities of clear centrifuged urine with an equal amount of the anti-serum; this method can, in fact, be used for determining the type of pneumococcus present in the body. The appearance of this substance in the urine is an indication that the case is a severe one, and a progressive increase in amount is a bad prognostic sign.

It may be noted here, in conclusion, that in man immunity against pneumonia may be short-lived, as in a good many cases of pneumonia a history of a previous attack is elicited.

The difficulty of interpreting the various serological facts observed in pneumonic conditions has led Lamar to investigate the action of certain chemical bodies, belonging to the soaps, on pneumococci. Welch long ago observed changes in the protoplasm of pneumococci in pneumonic exudates, pointing to the occurrence of lysis. Lamar has found that pneumococci treated with sodium oleate and especially with potassium soaps of acids having a high iodine value—*e.g.*, linoleic and linolenic acids—undergo morphological changes and become more subject to autolysis and more sensitive to the lytic action of sera, the latter being especially evident when immune sera are employed. The action of the soap is probably exerted on the lipoidal moiety of the bacterial cells, which are thus rendered more pervious to the serum constituents. There is evidence, however, that the protein constituents of sera exercise an inhibitory effect on the lytic action of the soaps, and Lamar has made the interesting observation that this inhibitory action can to a certain extent be neutralised by the use of boric acid. These observations are of the highest importance, and there is some experimental evidence that they may form the basis for a therapeutic treatment of pneumococcic infections. That they have a bearing on the explanation of natural recovery from such infections is indicated by the fact that in inflammatory exudations soaps form a definite constituent.

Vaccine therapy in pneumonia.—It may be stated here that vaccine therapy has been applied in the treatment of pneumonia, 20 to 30 millions of a stock vaccine being administered pending the preparation of an autogenous vaccine from cultures of the infecting strain made from material obtained by puncture of the pneumonic lung. Needless to say, the greatest care and judgment are necessary in the use of such vaccines. In certain cases there has been apparently a good result, but in others there is no evidence that the chance of survival has been greater than when ordinary treatment is applied. Something may be said for a combined treatment with serum and vaccine by the use of sensitised dead bacteria on the lines already described in dealing with streptococcic infections. Further, Rosenow has used as a vaccine pneumococci from which certain toxic properties have been removed by treatment with normal saline.

Prophylactic Vaccination.—In the South African mines a special situation exists in consequence of the great susceptibility to pneumonia occurring in the native labourers, who are chiefly recruited from subtropical regions. As the case incidence may run from 30 to 150 per thousand per annum, and the mortality from 10 to 30 per thousand, the disease is a very serious one. Almroth Wright introduced prophylactic vaccination, and Lister, founding on his investigations (*v. supra*), pre-

pared a vaccine containing the three prevalent types of the pneumococcus. In the latest applications of the method three injections at seven-day intervals of, in all, 7000 million bacterial bodies, killed by an antiseptic, were administered. A very marked diminution in the incidence of the disease has followed.

Methods of Examination.—In stained films of sputum, pus, or other exudate containing pneumococci, the outstanding feature is the predominance of diplococcal forms the elements of which may have a lanceolate shape and which are Gram-positive. Often a capsule stain demonstrates the capsule in such material, and it may even appear stained in Gram films. Cultures on blood agar should be made which after 24 hours at 37° C. will, if the pneumococcus be present, show characteristic colonies. Subcultures on serum bouillon or serum-smeared agar will show capsulation. Bile-solubility and reaction with inulin may be tested; if advisable a white mouse may be inoculated to test the pathogenicity and to afford in blood films corroborative evidence of capsulation.

Occurrence of Other Organisms in Pneumonia.

As might be expected, seeing that pneumonia is merely an inflammation occurring in a special tissue, organisms other than the pneumococcus have been found associated with the disease, but in not more than about 5 per cent. of cases in all. The chief of these are the streptococcus pyogenes, b. influenzæ, Friedländer's pneumobacillus, b. coli (rarely); mixed infections with these and with the pneumococcus also occur. Of the organisms named the pneumobacillus is of historic interest, as it was the first organism described in pneumonia, though there is little doubt that in early days it was often confused with the pneumococcus.

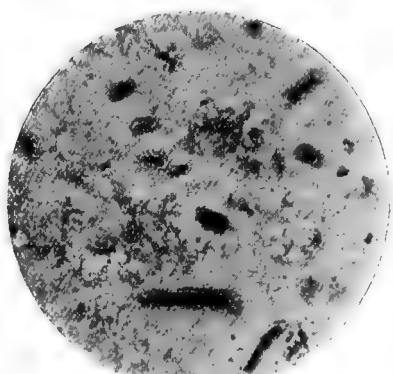

Fig. 62.—Friedländer's pneumobacillus, showing the variations in length, also capsules. Film preparation from exudate in a case of pneumonia. ×1000.

Friedländer's pneumobacillus.—This organism does not occur alone in more than about one per cent. of cases of pneumonia. In the sputum it may appear as a very short diplobacillus possessing a capsule, but it also frequently is seen in the form of long rods (Fig. 62). It stains by ordinary methods, but *loses the stain in Gram's method.*

It can be easily isolated on agar plates, on which it forms large whitish moist colonies resembling knobs of ivory. On gelatine stabs, at the site of the puncture the growth is sometimes heaped up above the level of the medium, and along the needle track there is a white granular appearance, so that the whole may resemble a white round-headed nail driven into the gelatin (Fig. 63), but this appearance is not so frequent as it is often stated to be. The gelatin is not liquefied. The organism grows well on all ordinary media, and on these its bacillary nature is in marked evidence (Fig. 64). It may form capsules in serum bouillon. It is non-motile. It ferments glucose, lactose, maltose, and mannite with acid and gas formation; the amount of acid formed from lactose is often insufficient to clot milk. It usually can form indol from peptone. The pneumobacillus is probably closely related to the b. coli.

FIG. 63.—Stab culture of Friedländer's pneumobacillus in peptone gelatin, showing the nail-like appearance; ten days' growth. Natural size.

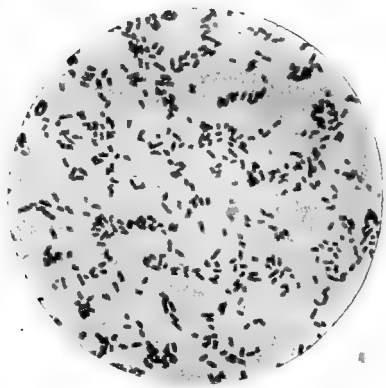

FIG. 64.—Friedländer's pneumobacillus,[1] from a young culture on agar, showing some rod-shaped forms. Stained with thionin-blue. ×1000.

When injected into mice and guinea-pigs it originates a septicæmia and

[1] The apparent size of this organism, on account of the nature of its sheath, varies much according to the stain used. If stained with a strong stain, *e.g.*, carbol-fuchsin, its thickness appears nearly twice as great as is shown in the figure.

can be seen in the heart blood to possess capsules. It is less pathogenic to rabbits and dogs, but when injected into the trachea in these animals it originates a pneumonia. As stated above, it is the only organism present in a small number of cases of human pneumonia, and it has also been isolated from conditions of empyema, meningitis, appendicitis, and pyæmia; a bacillus closely related or identical has been found in rhinoscleroma (*q.v.*). It is a not infrequent inhabitant of the mouth and nose of healthy individuals. From its historical associations an altogether undue importance has been attached to this bacillus.

In septic pneumonias the ordinary pyogenic bacteria, alone or associated with the pneumococcus, are found.

Epidemic Cerebro-Spinal Meningitis or Cerebro-Spinal Fever.

As the result of observations on this disease in different parts of the world, it has been now established that the causal agent is the *diplococcus intracellularis meningitidis*, first described by Weichselbaum, and now usually known as the *meningococcus*. This organism is a small coccus measuring about 1 μ in diameter; it usually occurs in pairs, the adjacent sides being somewhat flattened against each other. In most cases the cocci are chiefly contained within polymorphonuclear leucocytes in the exudation (Fig. 65); in some cases, however, the majority may be lying free. It stains readily with basic aniline dyes, but loses the stain in Gram's method. Both in appearance and in its staining reactions it is closely similar to the gonococcus (*vide* p. 255). The organism can readily be cultivated outside the body, but the conditions of growth are somewhat restricted—"trypagar" (p. 43), agar with an admixture of serum, ascitic fluid, or blood (p. 45) is to be recommended. The optimum reaction is one neutral to phenol-phthalein. Growth takes place

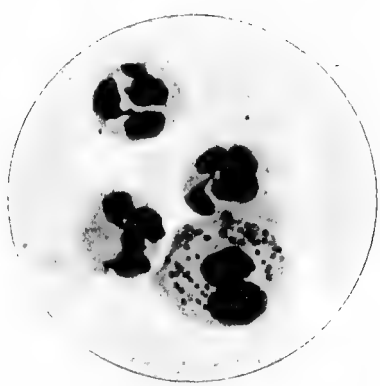

Fig. 65.—Film preparation of exudation from a case of meningitis, showing the meningococci within leucocytes. See also Plate I., Fig. 3.
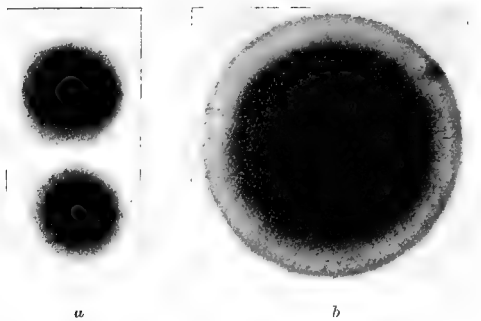
Stained with carbol-thionin-blue. ×1000.

best at the temperature of the body, and practically ceases at 25° C. On these media the colonies are circular discs with a slightly opaque centre fading into a delicate transparent margin (Fig. 66), and they have a smooth, shining surface; they have a slightly mucoid consistence and readily emulsify in water or normal saline. When examined under a low magnification the centre appears somewhat yellowish, and the margins usually are smooth and quite regular; at a later period of growth slight crenation may appear, especially when the medium is somewhat dry. The colonies may be of considerable size, reaching sometimes a diameter of 2 to 3 mm. on the second day. A stroke



a *b*

FIG. 66.—*a*. Two-day colonies of the meningococcus on Martin's medium (p. 43), ×9; *b*. the same, in which illumination has been arranged to show finely granular centre and transparent margin, ×12. Compare with Fig. 69.
From photographs by Dr. W. B. M. Martin.

culture gives a broad line of growth of similar character; the margins tend to be somewhat crenated, and isolated colonies often occur. On plain agar the colonies are very much smaller, and sometimes no growth occurs; sub-cultures especially often fail to give any growth on this medium. In serum bouillon the organism produces a general turbidity with formation of some deposit after a day or two. It ferments maltose and dextrose with acid production, a property which distinguishes it from the micrococcus catarrhalis (*vide infra*); it has no action on saccharose. Fermentation tests can be carried out by means of either fluid or solid media containing 1 per cent. of the sugar to be tested, along with neutral-red or litmus as an indicator (p. 79). In cultures the organism presents the same appearance as in the body, and often shows tetrad formation. There is also a

great tendency to the production of involution forms (Fig. 67), many of the cocci becoming much swollen, staining badly, and afterwards undergoing disintegration. This change, according to Flexner's observations, would appear to be due to the production of an autolytic enzyme, and he has also found that this substance has the property of producing dissolution of the bodies of other bacteria. The life of the organism in cultures is a comparatively short one; after a few days cultures will often be found to be dead, but, by making sub-cultures every three or four days, strains can be maintained alive for considerable periods. On egg medium (p. 46), however, it survives for a considerable time. The organism is readily killed by heat at 60° C., and it is also very sensitive to weak antiseptics; drying for a period of a day has been found to be fatal to it. The facts established accordingly show it to be a somewhat delicate parasite.

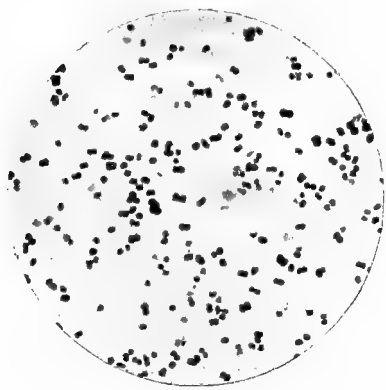


FIG. 67.—Pure culture of diplococcus intracellularis, showing involution forms.

As stated above, the organism occurs in the exudate in the meninges and in the cerebro-spinal fluid, and it can usually be obtained by lumbar puncture. In acute cases, especially in the earlier stages, it is usually abundant; but in the later stages of cases of more sub-acute character, its detection may be a matter of difficulty, and only a few examples may be found after a prolonged search. But it should be recognised that *at any stage* microscopic examination and even cultivation may sometimes give a negative result. In most cases the lesions are practically restricted to the nervous system, but occasionally complications occur, and in these the organism may be present. It has been found, for example, in arthritis, pericarditis, pneumonic patches in the lung, and in other inflammatory conditions associated with the disease, and also occasionally in purpuric patches in the skin, though the ordinary petechial eruption is of toxic origin. In a small proportion of cases it may be obtained from the blood during life.

Experimental inoculation shows that the ordinary laboratory animals are relatively insusceptible to this organism. An inflammatory condition may be produced in mice and guinea-pigs by intra-peritoneal injection, and a fatal result with symptoms of collapse may follow; in such cases the organism does not seem to undergo very active multiplication, though it may sometimes be cultivated from the blood, and none of the lesions in the nervous system are reproduced. Similar results are produced by the endotoxin in dead cultures, and occasionally the lethal dose of the dead organisms may equal that of the living (Gordon). There is thus evidence that an active endotoxin plays an important part in the pathology of the disease. Flexner and also Stuart M'Donald have shown that cerebro-spinal meningitis may be produced in monkeys by injections of the organism into the spinal canal, the latter observer finding that exudate containing meningococci was more effective than cultures. In such experiments the organism extends upwards to the brain, and produces meningitis within a very short time. The resulting lesions, both as regards their distribution and general characters, and also as regards the histological changes, resemble the disease in the human subject. Even these animals, however, are manifestly less susceptible than the human subject.

The meningococcus can usually be found in the naso-pharynx of patients suffering from the disease, and there is no doubt that this is the usual channel of infection. In cases where recovery occurs, the organism may persist for a varying period of time,—usually only for a week or two, but sometimes for months. There is difference of opinion as to the route by which the organism passes from the naso-pharynx to the meninges. One view is that it passes directly by the lymphatics to the base of the brain, but satisfactory evidence of this is wanting. The other view is that it passes by the blood stream; this is in accordance with what occurs in other infections, and is also supported by the fact that in some very acute cases with purpuric eruption, it has been found in the blood before meningeal symptoms have appeared, and also occasionally in septicæmic types without meningitis. For a considerable time it has been known that contacts with cases of cerebro-spinal fever often harbour the meningococcus in the naso-pharynx, that is, are "carriers," and during the war this subject has been extensively investigated. In fact, the examination of contacts has become a routine procedure. The percentage of "positives" amongst contacts varies; sometimes it has been found to be twenty or even higher. Non-contacts also have been examined during epidemics, and amongst them also a considerable proportion, though not so great as amongst contacts, have been found to be carriers. In some carriers the organism occurs sparsely amongst other organisms, but in others in fairly large proportion, and occasionally in almost pure culture. In the great

majority of carriers the organism can be found for only a comparatively short time—a few days even, or a week or two—but in a small proportion it persists for months, these being "chronic" carriers. Such individuals will, of course, act in maintaining the source of the infection, and it appears that the occurrence of an epidemic disease depends upon a dissemination of the organism through the community as evidenced by a high carrier rate, though the conditions which lead to the dissemination are not understood. Unfortunately we have at present no ready means of estimating the relative virulence of meningococci obtained from the naso-pharynx and from elsewhere. With regard to the epidemiology two facts are of importance. One is that direct infection of a healthy individual from a patient suffering from the disease is comparatively uncommon, though it sometimes occurs; the other is that it is rare for a known carrier to develop the disease. On the other hand, there is substantial evidence of persons being infected from carriers. The facts mentioned would seem to show that the organism is spread widely from individual to individual, in most cases without result, but that when the organism reaches a susceptible individual the disease may rapidly develop. No doubt the number of the organisms in the naso-pharynx is a factor of importance, heavy carriers being especially dangerous. It has been stated by some observers that the presence of the meningococcus leads to, or is associated with, pharyngeal catarrh, and that this often precedes meningeal infection. More extended observations, however, have thrown doubt on this, as it is certainly the case at least that the organism may abound in the naso-pharynx without the presence of catarrh or any abnormality. Manifestly the act of coughing, however, will aid in its diffusion when it is present.

Identification of the meningococcus.—In the case of meningitis, this usually presents no difficulty, as the finding of a Gram-negative diplococcus in the cerebro-spinal fluid is practically conclusive. In the case of the naso-pharynx, however, the matter is quite different. Means must be taken to distinguish the organism from others resembling it, which occur in the situation. Till recently, the following points taken together have been usually accepted as justifying a positive diagnosis: conformity in the microscopic characters and in the appearance of the colonies with those of the meningococcus, ready emulsification in saline, absence of growth on agar at 23° C., fermentation of glucose and maltose, and non-fermentation of saccharose. Attempts have been made to obtain identification by means of agglutination, and in this connection the work of Gordon has been of high value. On examining meningococci from various cases of meningitis, he found that a serum prepared by injecting any one strain did not agglutinate all the strains separated. Proceeding further and

preparing sera for other strains which were not agglutinated, he arrived finally at the recognition of four "types" (I.–IV.), according to agglutinating tests, cross agglutination between them being little marked. Of these, types I. and II. are the commonest, the latter being rather the more frequent. All the strains separated from cases of meningitis have been found to be agglutinated by one of the four sera. The inference is that diplococci otherwise like meningococci, which are not agglutinated by any of the type sera, are without pathogenic significance, and are not accepted as true meningococci. Gordon's results have so far received sound confirmation from the labours of those engaged in the examination of military cases. Manifestly if a strain were isolated from the cerebro-spinal fluid in a case of meningitis which did not conform to any of the types, a new type would have to be added.

Preparation of Agglutinating Sera.—Hine has devised the following method in the case of meningococci. A rabbit receives on one day three intravenous injections of five hundred millions of dead meningococci, with an interval of an hour between the injections; six days afterwards it receives a single dose of three thousand millions. On the eighth day the serum has usually a titre of over 1 : 800. Young rabbits of about a kilogramme in weight give the best results. The sera as supplied by the Central Cerebro-spinal Fever Laboratory are used in four dilutions, to each of which equal amounts of emulsion of the organism to be tested are added, the ultimate dilutions of serum being 1 : 50, 1 : 100, 1 : 200, 1 : 400. Emulsions of known type organisms are used as controls at the same time. After the mixtures are made they are put in a chamber at 55° C. for twenty-four hours, and the results are then read.

Apart from the epidemic form of the disease, cases of a sporadic nature also occur, in which the lesions are of the same nature, and in which the meningococcus is present. The facts stated would indicate that the origin and spread of the disease in the epidemic form depend on certain unknown conditions which produce an increased virulence of the organism. In simple posterior basal meningitis in children a diplococcus is present, as described by Still, which has the same microscopic and cultural characters as the diplococcus intracellularis; it has been regarded as probably an attenuated variety of the latter. Houston and Rankin have found that the serum of a patient suffering from epidemic meningitis does not exert the same opsonic and agglutinative effects on the diplococcus of basal meningitis as on the diplococcus intracellularis; and this result points to the two organisms being distinct, though closely allied, species.

Serum Reactions.—An agglutination reaction towards the meningococcus is given by the serum of patients suffering from the disease, when life is prolonged for a sufficient length of time. It usually appears about the fourth day, when the serum may give a positive reaction in a dilution of 1 : 50; at a later stage it has been observed in so great a dilution as 1 : 1000. Specific opsonins may appear in the blood about the same time, and though they are not always proportional in amount to the agglutinins, the two classes of substances have pretty much the same

significance, and may occasionally be of use in diagnosis when lumbar puncture fails to give positive results. Although their presence in large amounts may be said to indicate a marked reaction, they do not supply information of much value in relation to prognosis. Immune-bodies, as shown by bactericidal and deviation of complement tests (pp. 122, 127), may also be developed in considerable amount in the course of the disease.

Anti-sera for therapeutical purposes have been introduced by various workers, and of these the one which has been most extensively used is that of Flexner and Jobling. This serum is prepared from the horse by repeated injections in increasing doses of dead cultures, followed by injections of culture autolysate and of living cultures, these two latter being best administered by the subcutaneous method. Several strains of meningococci are mixed together for purposes of injection, and the immunisation is continued over a period of several months. For treatment of the disease the serum is injected under the spinal dura, 30 c.c. being generally used for an injection in an adult, this being repeated on subsequent days. Some of the spinal fluid is removed and then the serum is injected, undue pressure being avoided. This serum has been used on a large scale in various parts of the world, and there is general agreement as to its favourable effects—the mortality of the disease, which is generally 70 to 80 per cent., having been reduced to about 30 per cent. or even less. By means of its use the tendency to the occurrence of chronic lesions has also been markedly diminished. The action of such anti-sera cannot as yet be fully explained. They certainly contain opsonins, agglutinins, immune-bodies which bind complement, and possibly also anti-endotoxins. After the injection the number of meningococci becomes markedly reduced, probably as a result of increased phagocytosis; there can scarcely be any direct bactericidal action owing to the absence of complement. Recently, monovalent sera against each of the four types of meningococcus (p. 250) and also a polyvalent serum have been prepared for military cases by Gordon and his co-workers. The standardisation of such anti-sera is a matter of some difficulty; at first the deviation of complement method was used (p. 127), but now the opsonic index is regarded with more favour as an index of the potency of the serum. Gordon has recently pointed out the importance of estimating the anti-endotoxic action, and has described a method for this purpose.

Mackenzie and Martin treated cases by the intra-spinal injection of the fresh serum of patients suffering from the disease or who have recovered from it, such serum being in many cases rich in immune-bodies for the

meningococcus, and possessing a greatly increased bactericidal action as compared with normal serum. Though the number of cases treated by this method was not large, a distinctly favourable result was obtained.

Allied Diplococci.—In the naso-pharynx there occur other Gram-negative diplococci which morphologically have a close resemblance to the meningococcus. Many of these are chromogenic, *e.g.*, *m. catarrhalis flavus*, and can thus be readily distinguished; others differ in their fermentative actions. Of these latter the *diplococcus* or *micrococcus catarrhalis* has the closest resemblance to the diplococcus intracellularis. In addition to occurring in health this organism has also been found in large numbers in catarrhal conditions of the pharynx and respiratory passages. Its microscopic appearances are practically similar to those described above, and it also occurs within leucocytes. Its colonies on serum agar, though on the whole they tend to be rather more opaque, closely resemble those of the meningococcus. The organism usually grows on gelatin at 20° C. without liquefying the medium, and it has none of the fermentative properties described above as belonging to the diplococcus intracellularis. The *diplococcus pharyngis siccus* (v. Lingelsheim) grows at room temperature, and its colonies are very tough and adhere to the surface of the medium; it can thus readily be distinguished from the meningococcus. It has marked fermentative properties, acting on glucose, maltose, saccharose, and lævulose. The *diplococcus mucosus* has colonies of slimy consistence; it grows at room temperature, and it forms capsules, which can be demonstrated by the method of Hiss. The points of difference between the meningococcus and the gonococcus are given on p. 258. There are various other Gram-negative species of diplococci, which can be readily distinguished, and which have no pathogenic importance so far as is known. A Gram-positive diplococcus called the *diplococcus crassus* is also of common occurrence; it is rather larger than the diplococcus intracellularis, and especially in sub-cultures may tend to assume staphylococcal forms.

Meningitis due to other Organisms.—Meningitis may also be produced by almost any of the organisms described in the previous chapter, as associated with inflammatory conditions. A considerable number of cases, especially in children, are due to the *pneumococcus*. In many instances where no other lesions are present the extension is by the Eustachian tube to the middle ear. In other cases the path of infection is from some other lesion by means of the blood stream. This organism also infects the meninges not infrequently in lobar pneumonia, and in some

cases with head symptoms we have found it present where there was merely a condition of congestion. Occasionally epidemics of meningitis have been due to the pneumococcus. The *pneumo-bacillus* also has been found in a few cases. Meningitis is not infrequently produced by *streptococci*, especially when middle-ear disease is present, less frequently by one of the staphylococci; occasionally more than one organism may be concerned. In meningitis following influenza the *influenza bacillus* has been found in a few instances, but sometimes the pneumococcus is the causal agent. Sporadic cases of meningitis occur associated with organisms which resemble the influenza bacillus morphologically and also in presenting hæmophilic culture reactions, but which possess pathogenic properties for rabbits and guinea-pigs. Both in the cerebro-spinal fluid and in cultures, these bacilli frequently show a tendency to produce long filamentous forms and also may show a beading of the protoplasm, which gives them a diphtheroid appearance. The cases from which such bacilli have been isolated have chiefly occurred in children, are extremely fatal, and probably often follow on an otitis media, from which condition similar organisms have been isolated. Sometimes the meningitis is part of a septicæmic or pyæmic process,—in the latter the joints are often affected. It is impossible at present to say whether the organisms associated with such conditions are true influenza bacilli or are merely allied to them. They certainly tend to be more widely distributed in the body of the infected individual than is the case in the disease known clinically as influenza. On the other hand, influenza appears under several forms, and considerable variations may exist in the virulence of strains responsible for different outbreaks. An invasion of the meninges by the *anthrax bacillus* occurs, but is a rare condition; it is attended by diffuse hæmorrhage in the sub-arachnoid space. In tubercular meningitis the *tubercle bacillus*, of course, is present, especially in the nodules along the sheaths of the vessels.

In conclusion, it may be stated that *mixed infections* may occur in meningitis. Thus the pneumococcus has been found associated with the tubercle bacillus and also with the meningococcus, sometimes appearing as an additional infection to the latter.

Methods of Examination.—During life these involve the microscopic investigation of the centrifuged cerebro-spinal fluid and making cultures therefrom (p. 245). For the former, smears stained by carbol-thionin-blue and by Gram's method make the recognition of the meningococcus relatively easy, and the

presence of Gram-negative cocci, especially within cells, is practically diagnostic of a case of cerebro-spinal fever. Tubes of trypagar, serum agar (pp. 43, 45), or agar containing 25 per cent. of ascitic or ovarian fluid, may then be inoculated. The difficult cases are those where no bacteria can be found microscopically in the lumbar fluid. Here the character of the exudate may give help. A predominance of polymorphonuclear cells is usually manifest in meningococcic, pneumococcic, and influenzal cases, whereas in tubercular meningitis the exudate is, as a rule, chiefly lymphocytic, though polymorphs, often degenerated, also occur. In such circumstances, besides other media, a tube of blood-smeared agar should be inoculated in case the pneumococcus or the influenza bacillus is the causal organism. To speak generally, if with a polymorphonuclear exudate no growth occurs in the media mentioned, the case is most likely to be due to the meningococcus. The isolation of the organism from the naso-pharynx (p. 72) will give confirmatory, though of course not conclusive, evidence. It must be kept in view, however, that in meningitis high up, produced by any of the organisms mentioned, polymorph leucocytes may be present in the fluid obtained by lumbar puncture before the organisms themselves appear. In tubercular cases it is sometimes impossible to demonstrate the bacilli microscopically in the exudate, though on careful search they may usually be found.

For method of examination of the naso-pharynx *vide* p. 72.

CHAPTER IX.

GONORRHŒA AND SOFT SORE.

Gonorrhœa.

Introductory.—The micrococcus now known to be the cause of gonorrhœa, and called the *gonococcus*, was first described by Neisser, who in 1879 gave an account of its microscopical characters as seen in the pus of gonorrhœal affections, both of the urethra and of the conjunctiva. He considered that this organism was peculiar to the disease, and that its characters were distinctive. Later it was successfully isolated and cultivated on solidified human serum by Bumm and others. Its characters have since been minutely studied, and by inoculations of cultures on the human subject its causal relationship to the disease has been conclusively established.

The Gonococcus.—Microscopical Characters.—The organism of gonorrhœa is a small micrococcus which usually is seen in the diplococcus form, the adjacent margins of the two cocci being flattened, or even slightly concave, so that between them there is a small oval interval which does not stain. An appearance is thus presented which has been compared to that of two beans placed side by side (*vide* Fig. 68). When division takes place in the two members of a diplococcus, a tetrad is formed, which, however, soon separates into two sets of diplococci—that is to say, arrangement as diplococci is much commoner than as tetrads. Cocci in process of degeneration are seen as spherical elements of varying size, some being considerably swollen.

These organisms are found in large numbers in the pus of acute gonorrhœa, both in the male and female, and for the most part are contained within the leucocytes. In the earliest stage, when the secretion is glairy, a considerable number are lying free, or are adhering to the surface of desquamated epithelial cells, but when it becomes purulent the large proportion within leucocytes is a very striking feature. In the leucocytes they lie

within the protoplasm, especially superficially, and are often so numerous that the leucocytes appear to be filled with them, and their nuclei are obscured. As the disease becomes more chronic, the gonococci gradually become fewer, though even in long-standing cases they may still be found in considerable numbers. They are also present in the purulent secretion of gonorrhœal conjunctivitis, also in various parts of the female genital organs when these parts are the seat of true gonorrhœal infection, and they have been found in some cases in the secondary infections of the joints, as will be described below.

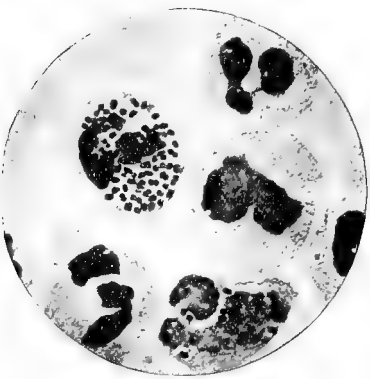

FIG. 68.—Portion of film of gonorrhœal pus, showing the characteristic arrangement of the gonococci within leucocytes. See also Plate I., Fig. 5.
Stained with fuchsin. ×1000.

Staining.—The gonococcus stains readily and deeply with a watery solution of any of the basic aniline dyes—methylene-blue, fuchsin, etc. It is, however, easily decolorised, and it completely loses the stain by Gram's method—an important point in the microscopical examination.

Cultivation of the Gonococcus.—This is attended with some difficulty, as the conditions of growth are somewhat restricted. The most suitable media are "blood-agar" and the serum media already described for the purpose (pp. 43, 45). It is advisable to inoculate the media within half-an-hour after obtaining the material from the body, and to place the tubes at once in the incubator. Growth takes place best at the temperature of the body, and ceases altogether at 25° C. Cultures are obtained by taking some pus on the loop of the platinum needle and inoculating one of the media mentioned by leaving minute quantities here and there on the surface. The medium may be used either as ordinary "sloped tubes" or as a thin layer in a Petri's capsule. The young colonies are usually visible within forty-eight hours, and often within twenty-four hours; it is important, however, to note that sometimes growth may not appear till the fourth day. They appear around the points of inoculation as small semi-transparent discs of rounded shape.

The colonies vary somewhat in size, and tend to remain more or less separate. Later, the margin tends to be undulated and the

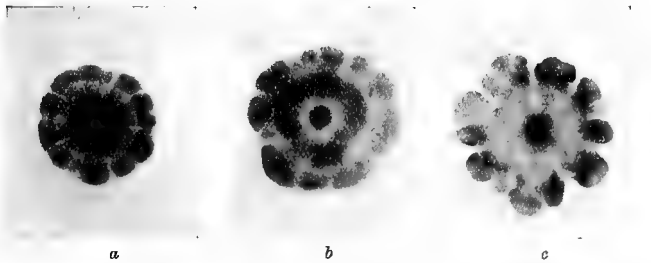

FIG. 69.—Colonies of gonococcus on serum-agar; (*a*) three days' growth; (*b*) and (*c*) five days' growth. ×9.
From photographs by Dr. W. B. M. Martin.

centre more opaque; a radial marking may be present (Fig. 69). The first cultures die out somewhat quickly, but in sub-cultures, kept at 37° C., the organism remains alive for a considerable time, sometimes three weeks. After about a week more active foci of growth may appear in some of the colonies in the form of heaped-up opaque-points, thus giving an appearance suggestive of contamination. In the early stage of the disease the organism is present in the male urethra in practically pure condition, and if the meatus of the urethra be sterilised by washing with weak solution of corrosive sublimate and then with absolute alcohol, and the material for inoculation be expressed from the deeper part of the urethra, cultures may often be obtained which are pure from the first. In culture, the organisms have similar microscopic characters to those described (Fig. 70), but show a remarkable tendency to

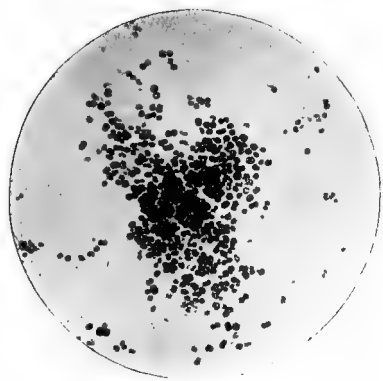

FIG. 70.—Gonococci, from a pure culture on blood-agar of twenty-four hours' growth. Some already are beginning to show the swollen appearance common in older cultures.
Stained with carbol-thionin-blue. ×1000.

undergo degeneration, becoming swollen and of various sizes, and staining very irregularly. Degenerated forms are seen even on the second day, whilst in a culture four or five days old comparatively few normal cocci may be found. The less suitable the medium the more rapidly does degeneration take place. When mixed with other organisms the gonococcus may be separated by serum-agar plates (p. 43).

On ordinary agar and on glycerin-agar some growth may take place when the reaction is just alkaline to litmus, but these media are quite unsuitable for ordinary purposes. The organism does not grow on gelatin, potato, etc.

Comparison with Meningococcus.—The morphological and cultural characters of the gonococcus and meningococcus are in many respects closely similar; the following points are of importance in distinguishing them. The conditions of growth of the gonococcus are more restricted than those of the meningococcus. The gonococcus usually does not grow on the ordinary agar media, whereas the meningococcus grows fairly well, at least after the first sub-culture. The colonies of the latter are rather more opaque and have more regular margins than those of the gonococcus. The meningococcus grows well in neutral bouillon, producing a general turbidity, whereas the gonococcus does not grow; even in serum bouillon the latter organism flourishes feebly, and the scanty growth falls to the bottom leaving the medium clear, whilst the meningococcus produces abundant growth with general turbidity. The fermentative effects have also been studied, and the chief results obtained are that glucose is the only sugar usually employed which is fermented by the gonococcus, whereas the meningococcus ferments maltose also. (For fermentative tests in the case of the gonococcus, solid media, as introduced by v. Lingelsheim, should be used, the serum medium of Martin, with litmus or neutral-red, and the particular sugar added, being specially suitable.)

Specific serum reactions — agglutination, opsonic action, bactericidal action, and fixation of complement—have been studied by Torrey, Elser and Huntoon, and Martin, in the case of the two organisms. The general results obtained are that each organism represents a somewhat heterogeneous group showing considerable variations as regards the tests mentioned (*vide* also p. 249). An anti-gonococcus serum produced by injecting one strain of gonococcus has the maximum effect on that strain, whilst its action on other strains may be much feebler. An anti-gonococcus serum may have some effect, usually slight, on a meningococcus and *vice versa*; this indicates that there are some receptors common to the two organisms. Arkwright finds that the complement-fixation test does not supply a satisfactory distinction between gonococci and meningococci.

Relations to the Disease.—The gonococcus is invariably present in the urethral discharge in gonorrhœa, and also in other parts of the genital tract when these are the seat of true gonorrhœal infection. Its presence in these different positions has been demonstrated not only by microscopical examination but also by culture. From the description of the conditions of growth in culture it will be seen that a life outside the body in natural conditions is practically impossible—a statement which corresponds with the clinical fact that the disease is always transmitted directly by contagion. Inoculations of pure cultures on the urethra of lower animals, and even of apes, is followed by no effect, but a similar statement can be made with regard to inoculations of gonorrhœal pus itself. In fact, hitherto it has been found impossible to reproduce the disease by any means in the lower animals. On a considerable number of occasions inoculations of pure cultures have been made on the human urethra, both on the male and female, and the disease, with all its characteristic symptoms, has resulted. (Such experiments have been performed independently by Bumm, Steinschneider, Wertheim, and others.) The causal relationship of the organism to the disease has therefore been completely established, and it is interesting to note how the conditions of growth and the pathogenic effects of the organism agree with the characters of the natural disease.

Intraperitoneal injections of pure cultures of the gonococcus in white mice produce a localised peritonitis with a small amount of suppuration, the organisms being found in large numbers in the leucocytes (Wertheim). They also penetrate the peritoneal lining and are found in the sub-endothelial connective tissue, but they appear to have little power of proliferation, they soon disappear, and the inflammatory condition does not spread. Injection of pure cultures into the joints of rabbits, dogs, and guinea-pigs causes an acute inflammation, which, however, soon subsides, whilst the gonococci rapidly die out; a practically similar result is obtained when dead cultures are used. These experiments show that while the organism, when present in large numbers, can produce a certain amount of inflammatory change in these animals, it has little or no power of multiplying and spreading in their tissues.

Toxin of the Gonococcus.—De Christmas has cultivated the gonococcus in a mixture of one part of ascitic fluid and three parts of bouillon, and has found that the fluid after twelve days' growth has toxic properties. At this period all the organisms are dead; such a fluid constitutes the "toxin." The toxic substances are precipitated along with the proteins by alcohol, and the precipitate after being desiccated possesses the toxic action. In young rabbits injection of the toxin produces suppuration; this is well seen in the anterior chamber of the eye, where hypopyon results. The most interesting point, however, is with regard to its action on mucous surfaces; for, while in the case of animals it produces no effect, its introduction into the human urethra causes acute catarrh,

attended with purulent discharge. He found that no tolerance to the toxin resulted after five successive injections at intervals. In a more recent publication he points out that the toxin on intracerebral injection has marked effects; he also claims to have produced an antitoxin. He states that the toxin diffuses out in the culture medium, and does not merely result from disentegration of the organisms. This has, however, been called in question by other investigators.

Distribution in the Tissues.—The gonococcus having been thus shown to be the direct cause of the disease, some additional facts may be given regarding its presence both in the primary and secondary lesions. In the human urethra the gonococci penetrate the mucous membrane, passing chiefly between the epithelial cells, causing a loosening and desquamation of many of the latter and inflammatory reaction in the tissues below, attended with great increase of secretion. There occurs also a gradually increasing emigration of leucocytes, which take up a large number of the organisms. The organisms also penetrate the subjacent connective tissue and are especially found, along with extensive leucocytic emigration, around the lacunæ. Here also many are contained within leucocytes. Even, however, when the gonococci have disappeared from the urethral discharge, they may still be present in the deeper part of the mucous membrane of the urethra, and also in the prostate, and may thus be capable of producing infection. The prostatic secretion may sometimes be examined by making pressure on the prostate from the rectum when the patient has almost emptied his bladder, the secretion being afterwards discharged along with the remaining urine (Foulerton). In acute gonorrhœa there is often a considerable degree of inflammatory affection of the prostate and vesiculæ seminales, but whether these conditions are always due to the presence of gonococci in the affected parts we have not at present the data for determining. A similar statement also applies to the occurrence of orchitis and also of cystitis in the early stage of gonorrhœa. Gonococci have, however, been obtained in pure culture from peri-urethral abscess and from epididymitis: it is likely that the latter condition, when occurring in gonorrhœa, is usually due to the actual presence of gonococci. During the more chronic stages other organisms may appear in the urethra, aid in maintaining the irritation, and may produce some of the secondary results. The bacillus coli, the pyogenic cocci, etc., are often present, and may extend along the urethra to the bladder and set up cystitis, though in this they may be aided by the passage of a catheter. It may be mentioned here that Wertheim cultivated the gonococcus from a case of chronic

gonorrhœa of two years' standing, and by inoculation on the human subject proved it to be still virulent.

In the disease in the female, gonococci are almost invariably present in the urethra, the situation affected next in frequency being the cervix uteri. They do not appear to infect the lining epithelium of the vagina of the adult unless some other abnormal condition be present, but they do so in the gonorrhœal vulvo-vaginitis of young subjects. They have also been found in suppurations in connection with Bartholini's glands, and sometimes produce an inflammatory condition of the mucous membrane of the body of the uterus. They may also pass along the Fallopian tubes and produce inflammation of the mucous membrane there. From the pus in cases of pyosalpinx they have been cultivated in a considerable number of cases. According to the results of various observers they are present in one out of four or five cases of this condition, usually unassociated with other organisms. Further, in a large proportion of the cases in which the gonococcus has not been found, no organisms of any kind have been obtained from the pus, and in these cases the gonococci may have been once present and have subsequently died out. Lastly, they may pass to the peritoneum and produce peritonitis, which is usually of a local character.

In *gonorrhœal conjunctivitis* the mode in which the gonococci spread through the epithelium to the subjacent connective tissue is closely analogous to what obtains in the case of the urethra. Their relation to the leucocytes in the purulent secretion is also the same. Microscopic examination of the secretion alone in acute cases often gives positive evidence, and pure cultures may be readily obtained. As the condition becomes more chronic, gonococci are less numerous and a greater proportion of other organisms may be present. Some observers have recently put forward the view that the "chlamydozoa" (p. 623) found in trachoma represent a mutation stage of the gonococcus, but there does not appear to be sufficient evidence that this is the case.

Relations to Joint-Affections, etc.—The relations of the gonococcus to the sequelæ of gonorrhœa form a subject of great interest and importance, and the application of recent methods of examination shows that the organism is much more frequently present in such conditions than the earlier results indicated. The following statements may be made with regard to them: First, in a large number of cases of arthritis following gonorrhœa pure cultures of the gonococcus may be obtained. A similar

statement applies to inflammation of the sheaths of tendons following gonorrhœa. Secondly, in a considerable proportion of cases no organisms have been found. It is, however, probable that in many of these the gonococci may have been present in the synovial membrane, as it has been observed that they may be much more numerous in that situation than in the fluid. Thirdly, in some cases, especially in those associated with extensive suppuration, occasionally of a pyæmic nature, various pyogenic cocci have been found to be present. In the instances in which the gonococcus has been found in the joints, the fluid present has usually been described as being of a whitish yellow tint, somewhat turbid, and containing shreds of fibrin-like material, though sometimes purulent in appearance. In one case Bordoni-Uffreduzzi cultivated the gonococcus from a joint-affection, and afterwards produced gonorrhœa in the human subject by inoculating with the cultures obtained. In another case, in which pleurisy was present along with arthritis, the gonococcus was cultivated from the fluid in the pleural cavity. The existence of a *gonorrhœal endocarditis* has been established by recent observations. Cases apparently of this nature occurring in the course of gonorrhœa had been previously described, but the complete bacteriological test has now been satisfied in several instances. In one case Lenhartz produced gonorrhœa in the human subject by inoculation with the organisms obtained from the vegetations. That a true *gonorrhœal septicæmia* may occur has also been established, cultures of the gonococcus having been obtained from the blood during life on more than one occasion (Thayer and Blumer, Thayer and Lazear, Ahmann).

Vaccines.—Both gonorrhœa itself and the secondary infections have been treated by means of vaccines, but the results reported vary greatly. On the whole most success has been obtained in the case of joint infections and allied conditions, though even here reports are contradictory. The initial dose employed has been usually about five million cocci, but care is necessary in starting the treatment, especially in the case of acute gonorrhœa. Harrison recommends that the organisms be killed by 0·5 per cent. carbolic acid instead of by heat.

Methods of Diagnosis.—For microscopical examination, dried films of the suspected pus, etc., may be stained by any of the simple solutions of the basic aniline stains. We prefer methylene- or thionin-blue, as they do not overstain, and the films do not need to be decolorised. Staining for one minute is sufficient. It is also advisable to stain by Gram's method, and it is a good plan to put at one margin of the cover glass a small quantity of culture of staphylococcus if available, in order to have a standard by which to be certain that the supposed gonococci are really decolorised. Regarding the value of microscopic examination alone, we may say that the presence in a urethral discharge of a large number of

micrococci having the characters, position, and staining reactions described above, is practically conclusive that the case is one of gonorrhœa. There is no other condition in which this sum-total of microscopical characters is present. We consider that it is sufficient for purposes of clinical diagnosis, and therefore of great value; in the acute stage a diagnosis can thus be made earlier than by any other method. The mistake of confusing gonorrhœa with such conditions as a urethral chancre with urethritis, will also be avoided. Even in chronic cases the typical picture is often well maintained, and microscopic examination alone may give a definite positive result. When other organisms are present, and especially when the gonococci are few in number, it is difficult, and in some cases impossible, to give a definite opinion, as a few gonococci mixed with other organisms cannot be recognised with certainty. This is often the condition in chronic gonorrhœa in the female. In the case of the female a drop of secretion should be taken on a platinum loop from the urethra or, with the aid of a speculum, from the cervix uteri, the adjacent parts being cleansed as far as possible by swabbing with sterile cotton wool. Microscopic examination, therefore, though often giving positive results, will sometimes be inconclusive. As regards lesions in other parts of the body, microscopic examination alone is quite insufficient; it is impossible, for example, to distinguish by this means the gonococcus from the meningococcus. Cultures alone supply the test, and the points above detailed are to be attended to.

Soft Sore.

The bacillus of soft sore was first described by Ducrey in 1889, who found it in the purulent discharge from the ulcerated surface; and later, in 1892, Unna described its appearance and distribution as seen in sections through the sores. The statements of these observers regarding the presence and characters of this organism have been fully confirmed by other observers.

Microscopical Characters.—The organism occurs in the form of minute oval rods measuring about 1·5 μ in length, and ·5 μ in thickness (Fig. 71). It is found mixed with other organisms in the purulent discharge from the surface, and is chiefly arranged in small groups or in short chains. When studied in sections through the ulcer, it is found in the superficial part of the floor, but more deeply situated than other organisms, and may be present in a state of purity amongst the leucocytic infiltration. In this position it is usually arranged in chains, which may be of considerable length, and which are often seen lying in parallel rows between the cells. The bacilli chiefly occur in the free condition, but occasionally a few may be contained within leucocytes.

There is no doubt that in many cases the organism is present in the buboes in a state of purity; it has been found there by microscopic examination, and cultures have also been obtained from this source. The negative results of some observers are

probably due to the organism having died off. On the whole the evidence goes to show that the ordinary bubo associated with soft sore is to be regarded as another lesion produced by Ducrey's bacillus. Sometimes the ordinary pyogenic organisms become superadded.

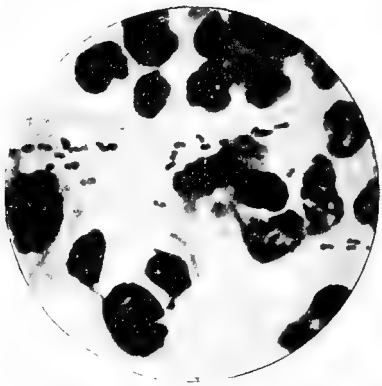

FIG. 71.—Film preparation of pus from soft chancre, showing Ducrey's bacillus, chiefly arranged in pairs. Stained with carbol-fuchsin and slightly decolorised. × 1500.

This bacillus takes up the basic aniline stains fairly readily, but loses the colour very rapidly when a decolorising agent is applied. Accordingly, in film preparations when dehydration is not required, it can be readily stained by most of the ordinary combinations, though Löffler's or Kühne's methylene-blue solutions are preferable, as they do not overstain. In sections, however, great care must be taken in the process of dehydration, and the aniline-oil method (*vide* p. 98) should be used for this purpose, as alcohol decolorises the organism very readily. A little of the methylene-blue or other stain may be added with advantage to the aniline oil used for dehydrating.

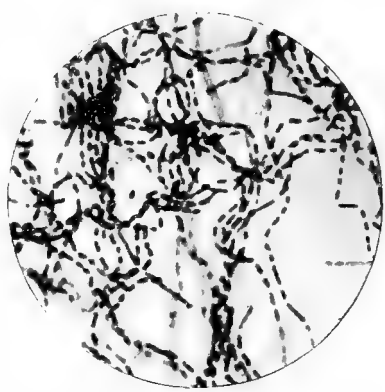

FIG. 72.—Ducrey's bacillus from a 24-hour culture in blood-bouillon. × 1500.[1]

Cultivation.—Although for a long period of time attempts to obtain cultures were unsuccessful, success has been attained within recent years. Benzançon, Griffon, and Le

[1] We are indebted to Dr. Davis for the use of Figs. 71 and 72.

Sourd obtained pure cultures in four cases, the medium used being a mixture of rabbit's blood and agar, in the proportion of one part of the former to two of the latter. The blood is added to the agar in the melted condition at 45° C., and the tubes are then sloped. Davis confirms these results, and finds that another good medium is freshly-drawn human blood distributed in small tubes; this method is specially suitable, as the blood inhibits the growth of various extraneous organisms. On the solid medium (blood-agar) the growth appears in the form of small round globules, which attain their complete development in forty-eight hours, having then a diameter of 1 to 2 mm.; the colonies do not become confluent. Microscopic examination of these colonies, which are dissociated with some difficulty, shows appearances similar to those observed when the organism is in the tissues (Fig. 72), but occasionally long undivided filaments are observed which Davis regards as degenerative forms. Within a comparatively short period cultures undergo marked degenerative changes, and great irregularities of form and shape are to be found. It would appear that a comparatively large amount of blood is necessary for the growth of this organism, and even sub-cultures on the ordinary media, including blood-serum media, give negative results. Inoculation of the ordinary laboratory animals is not attended by any result, but it has been found that some monkeys are susceptible, small ulcerations being produced by superficial inoculation, and in these the organism can be demonstrated. Tomasczewski cultivated the organism for several generations, and reproduced the disease by inoculation of the human subject. The causal relationship of this bacillus must therefore be considered as completely established, and the conditions under which it grows show it to be a strict parasite under natural conditions—a fact which is in conformity with the known facts as to the transmission of the disease.

CHAPTER X.

TUBERCULOSIS.

THE cause of tuberculosis was proved by Koch in 1882 to be the organism now universally known as the tubercle bacillus. Probably no other single discovery has had a more important effect on medical science and pathology than this. It has not only shown what is the real cause of the disease, but has also supplied infallible methods for determining which lesions are tubercular and which are not, and has also given the means of studying the modes and paths of infection. A definite answer has in this way been supplied to many questions which were previously the subject of endless discussion.

Historical.—By the work of Armanni and of Cohnheim and Salomonsen (1870-80) it had been demonstrated that tubercle was an infective disease. The latter observers found on inoculation of the anterior chamber of the eye of rabbits with tubercular material, that in many cases the results of irritation soon disappeared, but that after a period of incubation, usually about twenty-five days, small tubercular nodules appeared in the iris; afterwards the disease gradually spread, leading to a tubercular disorganisation of the globe of the eye. Later still, the lymphatic glands became involved, and finally the animal died of acute tuberculosis. The question remained as to the nature of the virus, the specific character of which was thus established, and this question was answered by the work of Koch.

The announcement of the discovery of the tubercle bacillus was made by Koch in March 1882, and a full account of his researches appeared in 1884 (*Mitth. a. d. K. Gsndhtsamte.*, Berlin). Koch's work on this subject will remain as a classical masterpiece of bacteriological research, both on account of the great difficulties which he successfully overcame and the completeness with which he demonstrated the relations of the organism to the disease. The two chief difficulties were, first, the demonstration of the bacilli in the tissues, and, secondly, the cultivation of the organism outside the body. For, with regard to the first, the tubercle bacillus cannot be demonstrated by a simple watery solution of a basic aniline dye, and it was only after prolonged staining for twenty-four hours, with a solution of methylene-blue with caustic potash added, that he was able to reveal the presence of the organism. Then, in the second place, all attempts to cultivate it on the ordinary media failed, and he succeeded in obtaining growth only on solidified blood serum, the method of preparing which he himself devised, inoculations being made on this medium from

the organs of animals artificially rendered tubercular. The fact that growth did not appear till the tenth day at the earliest, might easily have led to the hasty conclusion that no growth took place. All difficulties were, however, successfully overcome. He cultivated the organism by the above method from a great variety of sources, and by a large series of inoculation experiments on various animals, performed by different methods, he conclusively proved that bacilli from these different sources produced the same tubercular lesions and were really of the same species. His work was the means of showing conclusively that such conditions as lupus, "white swelling" of joints, scrofulous disease of glands, etc., are really tubercular in nature.

Tuberculosis in Animals.—Tuberculosis is not only the most widely spread of all diseases affecting the human subject, and produces a mortality greater than any other, but there is probably no other disease which affects the domestic animals so widely. We need not here describe in detail the various tubercular lesions in the human subject, but some facts regarding the disease in the lower animals may be given, as this subject is of great importance in relation to the infection of the human subject.

Amongst the domestic animals the disease is commonest in cattle (bovine tuberculosis), in which animals the lesions are very various, both in character and distribution. In most cases the lungs are affected, and contain numerous rounded nodules, many being of considerable size; these may be softened in the centre, but are usually of pretty firm consistence and may be calcified. There may be in addition caseous pneumonia, and also small tubercular granulations. Along with these changes in the lungs, the pleuræ are also often affected, and show numerous nodules, some of which may be of large size, firm and pedunculated, the condition being known in Germany as *Perlsucht*, in France as *pommelière*. Lesions similar to the last may be chiefly confined to the peritoneum and pleuræ. In other cases, again, the abdominal organs are principally involved. The udder becomes affected in a certain proportion of cases of tuberculosis in cows—in 3 per cent. according to Bang—but primary affection of this gland is very rare. Tuberculosis is also a comparatively common disease in pigs, in which animals it in many cases affects the abdominal organs, in other cases produces a sort of caseous pneumonia, and sometimes is met with as a chronic disease of the lymphatic glands, the so-called "scrofula" of pigs. Tubercular lesions in the muscles are less rare in pigs than in most other animals. In the horse the abdominal organs are usually the primary seat of the disease, the spleen being often enormously enlarged and crowded with nodules of various shapes and sizes; sometimes, however, the primary lesions are pulmonary. In sheep and goats tuberculosis is of rare occurrence, especially in the former animals. It may occur spontaneously in dogs, cats, and in the large carnivora. It is also sometimes met with in monkeys in confinement, and leads to a very rapid and widespread affection in these animals, the nodules having a special tendency to soften and break down into a pus-like fluid.

Tuberculosis in fowls (avian tuberculosis) is a common and very infectious disease, nearly all the birds in a poultry-yard being sometimes affected.

From these statements it will be seen that the disease in animals presents great variations in character, and may differ in many respects from that met with in the human subject. The relations of the different forms of tuberculosis are discussed below, but it may be stated here that two chief types of mammalian tubercle bacilli are now recognised—a *human type* which is the common cause of tuberculosis in the human subject, and a *bovine type* which produces bovine tuberculosis and also a certain proportion of cases of human tuberculosis. The description which follows applies to the *human type*.

Tubercle Bacillus (Human Type)—Microscopical Characters.—Tubercle bacilli are minute rods which usually measure 2·5 to 3·5 μ in length, and ·3 μ in thickness, *i.e.*, in proportion to their length they are comparatively thin organisms (Figs. 73 and 74). Sometimes, however, longer forms, up to 5 μ or more in length, are met with, both in cultures and in the tissues. They are straight or slightly curved, and are of uniform thickness, or may show slight swelling at their extremities. When stained they appear uniformly coloured, or may present small uncoloured spots along their course, with darkly stained parts between. There is no satisfactory evidence that such appearances represent spore-formation, as some have supposed; and it has been shown that "beaded" bacilli have no higher powers of resistance than those which stain uniformly.

FIG. 73.—Tubercle bacilli of the human type, from a pure culture on glycerin agar. Stained with carbol-fuchsin. ×1000.

The bacillus is seen in the "beaded" form when grown on media containing sperm or olive oil (A. H. Miller).

The bacilli in the tissues occur scattered irregularly or in little masses. They are usually single, or two are attached end to end and often form in such a case an obtuse angle. True chains are not formed, but occasionally short filaments are met with. In cultures the bacilli form masses in which the rods are closely applied to one another and arranged in a more or less parallel manner. Tubercle bacilli are quite devoid of motility.

Aberrant Forms.—Though such are the characters of the organism as usually met with, other appearances are sometimes found. In old cultures, for example, very much larger elements may occur. These may be in the form of long filaments, sometimes swollen or clubbed at their extremities, may be irregularly beaded, and may even show the appearance of branching. Such forms have been studied by Metchnikoff, Maffucci, Klein, and others. Their significance has been variously interpreted, for while some look upon them as degenerated or involution forms, others regard them as indicating a special phase in the life-history of the organism,

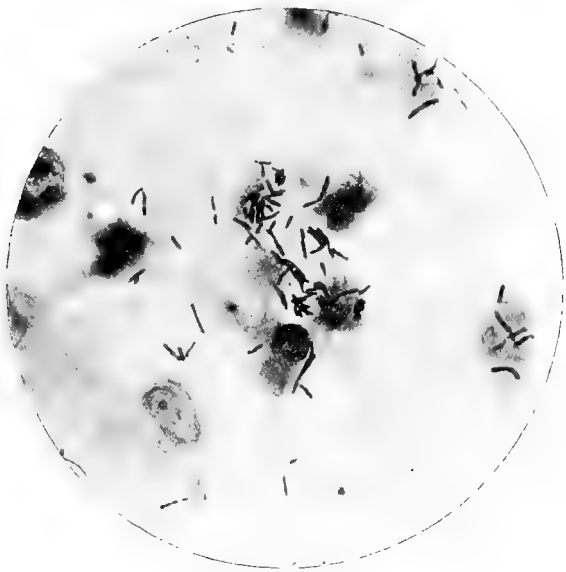

FIG. 74.—Tubercle bacilli in phthisical sputum ; they are longer than is often the case. See also Plate II., Fig. 7.
Film preparation, stained with carbol-fuchsin and methylene-blue.
× 1000.

allying it with the higher bacteria. Recent observations, however, go to establish the latter view, and this is now generally accepted by authorities. It has also been found that under certain circumstances tubercle bacilli in the tissues produce a radiating structure closely similar to that of the actinomyces. Club-like structures may be present at the periphery. This was found by Babès and also by Lubarsch to be the case when the bacilli were injected under the dura mater and directly into certain solid organs, such as the kidneys in the rabbit. Similar results obtained with other acid-fast bacilli will be mentioned below, and these organisms would appear to form a group closely allied to the streptothriceæ, the bacillary parasitic form being one stage of the life-history of the organism. This group is often spoken of as the *mycobacteria.*

Staining Reactions.—The tubercle bacillus takes up the ordinary stains very slowly and faintly, and for successful staining one of the most powerful solutions ought to be employed, *e.g.*, gentian-violet or fuchsin, along with aniline-oil water or solution of carbolic acid. Further, such staining solutions require to be applied for a long time, or the staining must be accelerated by heat, the solution being warmed till steam arises and the specimen allowed to remain in the hot stain for two or three minutes. One of the best and most convenient methods is the Ziehl-Neelsen method (see p. 105). The bacilli present this further peculiarity, however, that after staining has taken place they resist decolorising by solutions which readily remove the colour from the tissues and from other organisms which may be present. Such decolorising agents are sulphuric or nitric acid in 20 per cent. solution. Preparations can thus be obtained in which the tubercle bacilli alone are coloured by the stain first used, and the tissues can then be coloured by a contrast stain. Within recent years certain other bacilli have been discovered which present the same staining reactions as tubercle bacilli; they are therefore called "acid-fast" (*vide infra*). The spores of many bacilli become decolorised more readily than tubercle bacilli, though some retain the colour with equal tenacity.

Much's Method.—Much maintains that in addition to the ordinary acid-fast bacillus, the organism exists in the form of a bacillus which is not acid-fast and also in the form of free granules. These two forms are demonstrable by certain modifications of Gram's method, of which the following is specially suitable :—

Methyl-violet B.N., 10 c.c. of a saturated alcoholic solution in 100 c.c. of a 2 per cent. watery solution of carbolic acid ; stain by boiling over the flame for a few minutes or at 37° C. for 24–48 hours, then treat with Gram's iodine for 1–5 minutes, 5 per cent. nitric acid for one minute, 3 per cent. hydrochloric acid for 10 seconds, and complete the decolorisation with a mixture of acetone and alcohol in equal parts.

There seems to be no doubt that in certain conditions more tubercle bacilli can be demonstrated in the tissues by Much's method than by the Ziehl-Neelsen method.

Chemical Composition.—Bulloch and Macleod, by treating tubercle bacilli with hot alcohol and ether, extracted a wax which gave the characteristic staining reactions of the bacilli themselves. The remains of the bacilli, further, when extracted with caustic potash, yielded a body which was probably a chitin, and which was acid-fast when stained for twenty-four hours with carbol-fuchsin. Benians considers that a waxy material in some way encloses the protoplasm and fatty constituent, and confers on the organism the property of resisting the penetration of acid and alcohol.

Cultivation.—The medium first used by Koch was inspissated blood serum (*vide* p. 40). If inoculations are made on this

medium with tubercular material free from other organisms, there appear in from ten to fourteen days minute points of growth of dull whitish colour, rather irregular, and slightly raised above the surface (it is advisable to plant on the medium an actual piece of the tubercular tissue and to fix it in a break of the surface of the serum). Koch compared the appearance of these to that of small dry scales. In such cultures the growths usually reach only a comparatively small size and remain separate, becoming confluent only when many occur close together. In sub-cultures, however, growth is more luxuriant and may come to form a dull wrinkled film of whitish colour, which may cover the greater part of the surface of the serum and at the bottom of the tube may grow over the surface of the condensation water on to the glass (Fig. 75, A). The growth is always of a dull appearance, and has a considerable degree of consistence, so that it is difficult to dissociate a portion thoroughly in a drop of water. In older cultures the growth may acquire a slightly brownish or buff colour. When the small colonies are examined under a low power of the microscope, they are seen to be extending at the periphery in the form of wavy or sinuous streaks which radiate outward, and which have been compared to the flourishes of a pen. The central part shows similar markings closely interwoven. These streaks are composed of masses of the bacilli arranged in a more or less parallel manner.

FIG. 75.—Cultures of tubercle bacilli on glycerin agar.

A and B. Mammalian tubercle bacilli of human type; A is an old culture, B one of a few weeks' growth.

C. Avian tubercle bacilli. The growth is whiter and smoother on the surface than the others.

On Dorset's *egg medium* and especially on *glycerin egg*

medium the organism grows well, producing an abundant wrinkled layer which has usually a yellowish, buff, or pinkish colour. These media are specially suitable for direct cultivation from the tissues.

On *glycerin agar*, which was first introduced by Nocard and Roux as a medium for the culture of the tubercle bacillus, growth takes place in sub-cultures at an earlier date and progresses more rapidly than on serum, but this medium is not suitable for obtaining cultures from the tissues, inoculations with tubercular material usually yielding a negative result. The growth has practically the same characters as on serum. The organism also flourishes well on *glycerin potato*, and this medium is suitable for primary cultures from tubercular lesions. In *glycerin broth*, especially when the layer is not deep, tubercle bacilli grow readily in the form of little white masses, which fall to the bottom and form a powdery layer. If, however, the growth be started on the surface, it spreads superficially as a dull whitish wrinkled pellicle which may reach the walls of the flask; this mode of growth is specially suitable for the production of tuberculin (*vide infra*). The culture has a peculiar fruity and not unpleasant odour. On ordinary agar and on gelatin media no growth takes place. The use of animal tissues in glycerin bouillon as a medium for the growth of the tubercle bacillus has been introduced by Frugoni, and is one which gives excellent results. He recommends that small wedges of rabbit's lung should be sterilised in the autoclave, and placed in tubes of glycerin bouillon in such a way that their surface is kept moist by the medium, without the fragments being submerged. The growth is probably more rapid and luxuriant than in any other method.

The optimum temperature for growth is 37° to 38° C. Growth ceases about 42° and usually below 28°, but on long-continued cultivation outside the body and in special circumstances growth may take place at a lower temperature, *e.g.*, Sander found that growth took place in glycerin-potato broth even at 22° to 23° C.

Powers of Resistance.—Tubercle bacilli have considerable powers of resistance to external influences, and can retain their vitality for a long time outside the body in various conditions; in fact, in this respect they may be said to occupy an intermediate position between spores and spore-free bacilli. Dried phthisical sputum has been found to contain still virulent bacilli after two months, and similar results are obtained when the bacilli are kept in distilled water for several weeks.

So also they resist for a long time the action of putrefaction, which is rapidly fatal to many pathogenic organisms. Sputum has been found to contain living tubercle bacilli even after being allowed to putrefy for several weeks (Fraenkel, Baumgarten), and the bacilli have been found to be alive in tubercular organs which have been buried in the ground for a similar period. They are not killed by being exposed to the action of the gastric juice for six hours, or to a temperature of $-3°$ C. for three hours, even when this is repeated several times. It has been found that when completely dried they can resist a temperature of 100° C. for an hour, but, on the other hand, exposure in the moist condition to 70° C. for the same time is usually fatal. It may be stated that raising the temperature to 100° C. kills the bacilli in fluids and in tissues, but in the case of large masses of tissue care must be taken that this temperature is reached throughout. They are killed in less than a minute by exposure to .5 per cent. carbolic acid, and both Koch and Straus found that they are rapidly killed by being exposed to the action of direct sunlight.

Action on the Tissues.—The *local lesion* produced by the tubercle bacillus is the well-known tubercle nodule, the structure of which varies in different situations and according to the intensity of the action of the bacilli. After the bacilli gain entrance to a connective tissue such as that of the iris, their first action appears to be on the connective-tissue cells, which become somewhat swollen and undergo mitotic division, the resulting cells being distinguishable by their large size and pale nuclei—the so-called epithelioid cells. These proliferative changes may be well seen on the fifth day after inoculation or even earlier. A small focus of proliferated cells is thus formed in the neighbourhood of the bacilli, and about the same time numbers of leucocytes—chiefly lymphocytes—begin to appear at the periphery and gradually become more numerous. Soon, however, the action of the bacilli as cell-poisons comes into prominence. The epithelioid cells become swollen and somewhat hyaline, their outlines become indistinct, whilst their nucleus stains faintly, and ultimately loses the power of staining. The cells in the centre, thus altered, gradually become fused into a homogeneous substance, and this afterwards becomes somewhat granular in appearance. If the central necrosis does not take place quickly, then giant-cell formation may occur in the centre of the follicle, this constituting one of the characteristic features of the tubercular lesion; or after the occurrence of caseation giant-cells may be formed in the cellular tissue around. The centre of a giant-

cell often shows signs of degeneration, such as hyaline change and vacuolation, or it may be more granular than the rest of the cell. The exact mode of formation of a tubercle follicle varies, however, in different tissues.

Though there has been a considerable amount of discussion as to the mode of origin of the giant-cells, we think there can be little doubt that in most cases they result from enlargement of single epithelioid cells, the nucleus of which undergoes proliferation without the protoplasm dividing. These epithelioid cells may sometimes be the lining cells of capillaries. Some consider that the giant-cells result from a fusion of the epithelioid cells; but, though there are occasionally appearances which indicate such a mode of formation, it cannot be regarded as of common occurrence. In some cases of acute tuberculosis, when the bacilli become lodged in a capillary, the endothelial cells of its wall may proliferate, and thus a ring of nuclei may be seen round a small central thrombus. Such an occurrence gives rise to an appearance closely resembling a typical giant-cell. There can be no doubt that the cell necrosis and subsequent caseation depend upon the products of the bacilli, and are not due to the fact that the tubercle nodule is non-vascular. This non-vascularity itself is to be explained by the circumstance that young capillaries cannot grow into a part where tubercle bacilli are active, and that the already existing capillaries become thrombosed, owing to the action of the bacillary products on their walls, and ultimately disappear. At the periphery of tubercular lesions there may be considerable vascularity and new formation of capillaries.

The *general symptoms of tuberculosis*—pyrexia, perspiration, wasting, etc.—are to be ascribed to the absorption and distribution throughout the system of the toxic products of the bacilli; in the case of phthisical cavities and like conditions where other bacteria are present, the toxins of the latter also play an important part. The occurrence of amyloid change in the organs is believed by some to be chiefly due to the products of other, especially pyogenic, organisms, secondarily present in the tubercular lesions. This matter, however, requires further elucidation.

Presence and Distribution of the Bacilli.—A few facts may be stated regarding the presence of bacilli, and the numbers in which they are likely to be found in tubercular lesions. They are usually very few in number in chronic lesions, whether these are tubercle nodules with much connective-tissue formation or old caseous collections. In caseous material one can sometimes see a few bacilli faintly stained, along with very minute unequally stained granular points, some of which may possibly be spores of the bacilli. Whether they are spores or not, the important fact has been established, that tubercular material in which no bacilli can be found microscopically may be proved, on experimental inoculation into animals, to be

still virulent. In subacute lesions, with well-formed tubercle follicles and little caseation, the bacilli are generally scanty. They are most numerous in acute lesions, especially where caseation is rapidly spreading, for example, in such conditions as caseous catarrhal pneumonia (Fig. 76), acute tuberculosis of the spleen in children, which is often attended with a good deal of rapid caseous change, etc.; in such conditions they often form

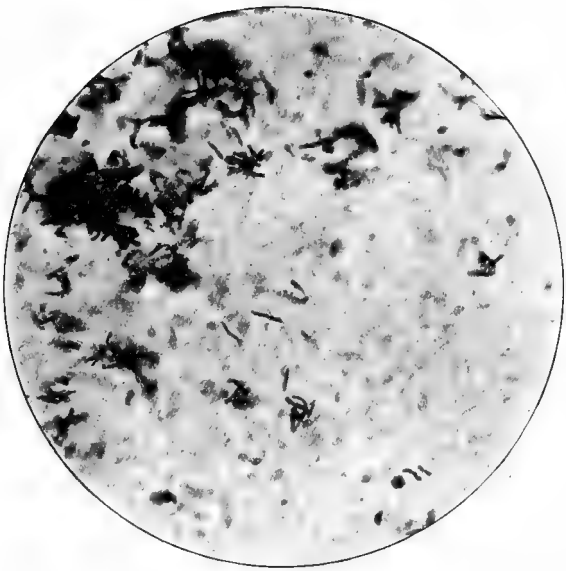

FIG. 76.—Tubercle bacilli in section of human lung in acute phthisis. The bacilli are seen lying singly, and also in large masses to left of field. The pale background is formed by caseous material. Stained with carbol-fuchsin and Bismarck-brown. ×1000.

large masses which are easily seen under a low power of the microscope. In acute miliary tuberculosis a few bacilli can generally be found in the centre of the follicles; but here they are often much more scanty than one would expect. The tubercle bacillus is one which not only has comparatively slow growth, but retains its form and staining power for a much longer period than most organisms. As a rule the bacilli are extra-cellular in position. Occasionally they occur within the giant-cells, in which they may be arranged in a somewhat radiate

manner at the periphery, occasionally also in epithelioid cells and in leucocytes.

The above statements, however, apply only to tuberculosis in the human subject, and even in this case there are exceptions. In the ox, on the other hand, the presence of tubercle bacilli within giant-cells is a very common occurrence; and it is also common to find them in considerable numbers scattered

FIG. 77.—Tubercle bacilli in giant-cells, showing the radiate arrangement at the periphery of the cells. Section of tubercular udder of cow.
Stained with carbol-fuchsin and Bismarck-brown. ×1000.

irregularly throughout the cellular connective tissue of the lesions, even when there is little or no caseation present (Fig. 77).

In tuberculosis in the horse and in avian tuberculosis the numbers of bacilli may be enormous, even in lesions which are not specially acute; and considerable variation both in their number and in their site is met with in tuberculosis of other animals.

In discharges from tubercular lesions which are breaking

down, tubercle bacilli are usually to be found. In the sputum of phthisical patients their presence can be demonstrated almost invariably at some period, and sometimes their numbers are very large (for method of staining, see p. 105). Several examinations may, however, require to be made; this should always be done before any conclusion as to the non-tubercular nature of a case is come to. In tubercular meningitis the bacilli can often be found in the cerebro-spinal fluid obtained by lumbar puncture. In cases of genito-urinary tuberculosis they are usually present in the urine; but as they are much diluted it is difficult to find them unless a deposit is obtained by means of the centrifuge. This deposit is examined in the same way as the sputum. The bacilli often occur in little clumps, as shown in Fig. 78. In tubercular ulceration of the intestine their presence in the fæces may be demonstrated, as was first shown by Koch; but in this case their discovery is usually of little importance, as the intestinal lesions, as a rule, occur only in advanced stages when diagnosis is no longer a matter of doubt.

Experimental Inoculation.—Tuberculosis can be artificially produced in animals in a great many different ways—by injection of the bacilli into the subcutaneous tissue, into the peritoneum, into the anterior chamber of the eye, into the veins; by feeding the animals with the bacilli; and, lastly, by making them inhale the bacilli suspended in the air.

The exact result, of course, varies in different animals and according to the method of inoculation, but we may state generally that when introduced into the tissues of a susceptible animal, the bacilli produce locally the lesions above described, terminating in caseation; that there occurs a tubercular affection of the neighbouring lymphatic glands, and that lastly there may be a rapid extension of the bacilli to other organs by the

blood stream and the production of general tuberculosis. Of the animals generally used for the purpose, the guinea-pig is most susceptible.

When a guinea-pig is inoculated subcutaneously with tubercle bacilli from a culture, or with material containing them, such as phthisical sputum, a local swelling gradually forms which is usually well marked about the tenth day. This swelling becomes softened and caseous, and may break down, leading to the formation of an irregular ulcerated area with caseous lining. The lymphatic glands in relation to the parts can generally be found to be enlarged and of somewhat firm consistence, about the end of the second or third week. Later, in them also caseous change occurs, and a similar condition may spread to other groups of glands in turn, passing also to those on the other side of the body. During the occurrence of these changes, the animal loses weight, gradually becomes cachectic, and ultimately dies, sometimes within six weeks, sometimes not for two or three months. *Post mortem*, in addition to the local and glandular changes, an acute tuberculosis is usually present, the spleen being specially affected. This organ is swollen, and is studded throughout by numerous tubercle nodules, which may be minute and grey, or larger and of a yellowish tint. If death has been long delayed, calcification may have occurred in some of the nodules. Tubercle nodules, though rather less numerous, are also present in the liver and in the lungs, the nodules in the latter organs being usually of smaller size though occasionally in large numbers. The extent of the general infection varies; sometimes the chronic glandular changes constitute the outstanding feature. Statements as to differences in the pathogenic effects of bacilli from human and bovine sources will be found below (p. 280).

Varieties of Tuberculosis.—1. *Human and Bovine Tuberculosis.*—Up till recent years it was generally accepted that all mammalian tuberculosis was due to the same organism, and, in particular, that tuberculosis could be transmitted from the ox to the human subject. The matter became one of special interest owing to Koch's address at the Tuberculosis Congress in 1901, in which he stated his conclusion that human and bovine tuberculosis are practically distinct, and that if a susceptibility of the human subject to the latter really exists, infection is of very rare occurrence,—so rare that it is not necessary to take any measures against it. Previously to this, Theobald Smith had pointed out differences between mammalian and bovine tubercle bacilli, the most striking being that the

latter possess a much higher virulence to the guinea-pig, rabbit, and other animals, and in particular that human tubercle bacilli, on inoculation into oxen, produce either no disease or only local lesions without any dissemination. Koch's conclusions were based chiefly on the result of his inoculations of the bovine species with human tubercle bacilli, the result being confirmatory of Smith's, and also on the supposition that infection of the human subject through the intestine is of very rare occurrence.

Since the time of Koch's communication an enormous amount of work has been done on this subject, and commissions of inquiry have been appointed in various countries. We may summarise the chief facts which have been established. Practically all observers are agreed that there are two chief types of tubercle bacilli, which differ both in their cultural characters and in their virulence — a bovine type and a human type. The bacilli of the bovine type, when cultivated, are usually shorter and thicker and more regular in size; whilst their growth on various culture media is scantier than that of the human type (Fig. 79). From the latter character the British Royal Commission have applied the term *dysgonic* to the bovine and *eugonic* to the human type. For distinguishing the growth characters of the two types egg media (p. 46) are especially suitable. On Dorset's medium the human type produces an abundant, dry and wrinkled or verrucose growth, which has often a yellowish or pinkish tint; while the bovine type forms a thin whitish layer, smooth or somewhat granular, rather moist in appearance, and the growth is much more easily broken up. The difference between the two types is accentuated by the

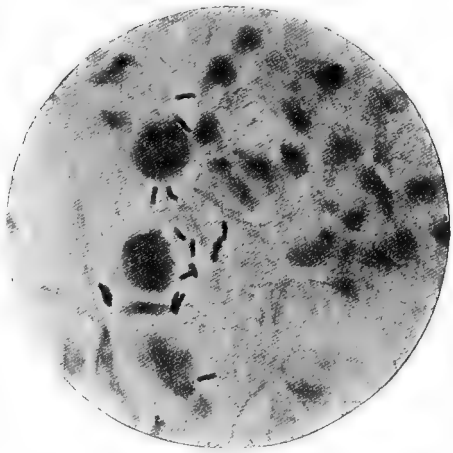

FIG. 79.—Bovine tubercle bacilli in milk. ×1000.

addition of glycerin to the medium; this greatly favours the growth of the human type, while it does not favour, or even inhibits, the growth of the bovine type. In fact, on glycerin-egg medium primary cultures of the latter often fail. These differences are most marked in the early cultures; in later sub-cultures they tend to diminish. The vitality of the bovine type is less on artificial media, cultures having sometimes a tendency to die out. As already stated, there is also a great difference in virulence towards the lower animals, the bacillus from the ox having a much higher virulence. This organism when injected in suitable quantities into the ox produces a local tubercular lesion, which is usually followed by a generalised and fatal tuberculosis; whereas injection of human tubercle bacilli produces no more than a local lesion, which undergoes retrogression. (In certain experiments, *e.g.*, those of Delépine, Hamilton, and Young, general tuberculosis has been produced in the bovine species by tubercle bacilli from the human subject, but these results are exceptional.) Corresponding differences come out in the case of the rabbit; in fact, intravenous injection of suitable quantities (*e.g.*, of 0·1–0·01 mgrm. of dried bacilli suspended in 1 c.c. of saline) in this animal is the readiest method of distinguishing the two types—an acute tuberculosis resulting with the bovine, but not with the human type. In guinea-pigs and monkeys a generalised tuberculosis may result from subcutaneous injection of bacilli of the human type, but in this case also the difference in favour of the greater virulence of the bovine type is made out. With regard to the distribution of the two types of organisms, it may be stated that, so far as we know, the bacillus obtained from bovine tuberculosis is

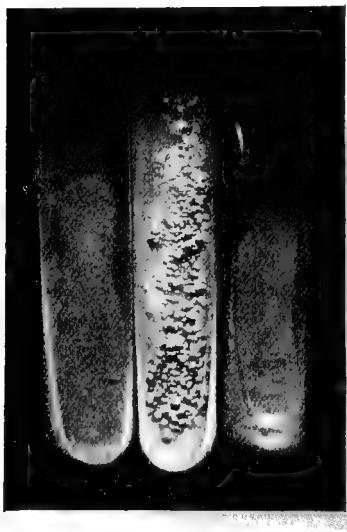

FIG. 80.—Cultures of bovine and human bacilli 5 weeks old on glycerin egg. The central tube is human, the tube on each side bovine. The three tubes were inoculated on the same day.

always of the bovine type; in fact this seems to be the prevalent organism in animal tuberculosis (*vide infra*). In human tuberculosis the bacilli in a large majority of the cases are of the human type; but, on the other hand, in a certain proportion bacilli of the bovine type are present. Pulmonary phthisis is almost invariably caused by bacilli of the human type; a few cases have been recorded in which the bovine type has been present, but these constitute less than 1 per cent. of the cases investigated. The Royal Commission found that the bovine type was present in 50 per cent. of cases of primary abdominal tuberculosis in children—that is, in cases where apparently infection had taken place by alimentation; and more recent observations have shown that glandular tuberculosis in children under ten years of age is produced by bovine bacilli in more than 70 per cent. of the cases. In cases of lupus nearly half of the bacilli obtained were of the bovine type, and it is an interesting fact that almost all the viruses, both of the human and bovine types, were markedly attenuated in their virulence for animals. In over two hundred cases of tuberculosis in children, given by W. H. Park, the bovine bacillus was present in more than 25 per cent., the percentage being higher in the earlier than in the later years of childhood; and Fraser has found that of seventy cases of tuberculosis of bones and joints in children in Edinburgh, this was the type present in more than half. This proportion is higher than that found by Eastwood and F. Griffith and by A. Stanley Griffith, in a large number of cases chiefly in England, namely, a little over 25 per cent. Fraser also found that the proportion of cases in which the bovine type is present is much higher when there is no evidence of infection from other members of the family, than when there is the possibility of such infection. Almost all the tubercular lesions from which the bovine type has been obtained have been in children, the presence of the bovine type of bacillus in adult tubercular lesions, phthisical sputum, etc., being of very rare occurrence. It is therefore justifiable to conclude that tuberculosis is transmissible from the ox to man, and that the milk of tubercular cows is a common vehicle of transmission.

Although most of the bacilli which have been cultivated correspond to one of the two types, as above described, it is also to be noted that intermediate varieties are occasionally met with, though some of these on analysis have been found to be really due to a mixture of the two types. According to some observers, it is possible to modify bacilli of the human type by passing them through the bodies of certain animals, *e.g.*, guinea-pigs, sheep, and goats, so that they acquire the characters of bovine bacilli, but the more recent results, including those of the Royal

Commission, are that this modification does not take place and that the characters of the type are comparatively stable. The question is still an open one, and it is doubtful whether or not a bovine type after long sojourn in the human tissues will assume the characters of the human type; if it does, the proportion of cases actually due to the bovine type will be of course larger than is indicated by the characters of the organism obtained from the lesion. It is quite likely that, although the bovine bacilli are more virulent to the lower animals than the human bacilli are, this does not also hold in the case of the human subject. In fact, the comparative chronicity of the primary abdominal lesions in children, in the first instance, would point rather to a low order of virulence towards the human subject. We may also add that there are cases, notably those of Ravenel, in which accidental inoculation of the human subject with bovine tubercle has resulted in the production of tuberculosis.

Some other facts obtained by the Royal Commission may be given. The bovine type of bacillus alone was found in the sheep, goat, and horse, whilst in the pig the bovine type was found in the great majority of cases, though in some the human type, and in others the avian tubercle bacillus, was present. In the case of these two latter the lesions were of a more localised kind. The bovine type was also found in the cat. The human type was found in animals in confinement, *e.g.*, the antelope, gnu, chimpanzee, and macacus rhœsus, and also in the parrot. The animals most susceptible to inoculation with the human type are the guinea-pig, rhœsus, and chimpanzee; the dog, rat, and mouse are practically immune, while the calf, rabbit, pig, and goat occupy an intermediate position. The parrot also has been found to be susceptible to inoculation with the human type. It was also shown that when cows were inoculated subcutaneously with considerable quantities of bacilli either of the human or bovine type the bacilli were excreted in the milk, and that in these cases the udder appeared normal. There is therefore the presumption that when during the course of the disease the bacilli are present in the blood stream, they may make the milk infective even though there are no lesions in the udder.

2. *Avian Tuberculosis.*—In the tubercular lesions in birds there are found bacilli which correspond in their staining reactions and in their morphological characters with those in mammals, but differences are observed in cultures, and also on experimental inoculation.

On glycerin agar and on serum, the growth of tubercle bacilli from birds is more luxuriant, has a moister appearance (Fig. 75, C), and, moreover, takes place at a higher temperature, 43·5° C., than is the case with mammalian tubercle bacilli. Experimental inoculation brings out even more distinct differences. Tubercle bacilli derived from the human subject or from the ox, for example, when injected into fowls, usually fail to produce tuberculosis, whilst those of avian origin very readily do so (on the other hand, the parrot is susceptible to inoculation with both mammalian types). Fowls are also very susceptible to the disease when fed with portions of the organs containing avian tubercle bacilli, but they can consume enormous quantities of phthisical sputum without becoming tubercular (Strauss, Wurtz, Nocard). The Royal Commission found that rabbits and mice are the only mammals susceptible to inoculation with avian tubercle bacilli, though others may succumb to

toxic effects when large doses are used. In the case of the rabbit, intravenous injection results in the formation of greyish-white foci in the spleen, but no true tubercles are formed; subcutaneous inoculation leads to a peculiar chronic disease in joints, testes, etc., whilst the liver and spleen are free from lesions—a result not obtained with mammalian bacilli.

There is, therefore, abundant evidence that the bacilli derived from the two classes of animals show important differences, and, reasoning from analogy, we might infer that probably the human subject also would be little susceptible to infection from avian tuberculosis. The question remains—Are these differences of a permanent character? Nocard found that mammalian bacilli of the human type when kept within closed collodion sacs in the peritoneal cavities of fowls over a long period of time, acquired the characters of avian bacilli, but the Royal Commission as the result of similar experiments obtained no evidence of such transformation. It is accordingly not possible at present to give a definite answer to the question.

3. *Tuberculosis in the Fish.*—Bataillon, Dubard, and Terre cultivated from a tubercle-like disease in a carp, a bacillus which, in staining reaction and microscopic characters, closely agrees with the tubercle bacillus. The lesion with which it was associated was an abundant growth of granulation tissue in which numerous giant-cells were present. It forms, however, luxuriant growth at the room temperature, the growth being thick and moist like that of avian tubercle bacilli (Fig. 82, *c*). Growth does not occur at the body temperature, though by gradual acclimatisation a small amount of growth has been obtained up to 36° C. Furthermore, the organism appears to undergo no multiplication when injected into the tissues of mammals, and attempts to modify this characteristic have so far been unsuccessful. Weber and Taute have cultivated this organism from mud, and also from organs of healthy frogs. It is thus probably to be regarded as a saprophyte which is only occasionally associated with disease in the fish.

According to the results of different experimenters, it is possible to modify human tubercle bacilli by allowing them to sojourn in the tissues of cold-blooded animals, *e.g.*, the frog, blind-worm, etc., so that they flourish at lower temperatures. These results have, however, been recently called in question, as it has been stated the organisms obtained were not modified tubercle bacilli, but other acid-fast bacilli which may be found in the tissues of normal cold-blooded animals. This question must accordingly be considered still an open one.

Other Acid-fast Bacilli.—Within recent years a number of bacilli presenting the same staining reaction as the tubercle

bacilli have been discovered. Such bacilli have a comparatively wide distribution in nature, as they have been obtained from various species of grass, from butter and milk, from manure, and from the surfaces of animal bodies. Microscopically, they agree more or less closely with tubercle bacilli, though most of them are shorter and plumper; many of them show filamentous and branching forms under certain conditions of culture. Moreover, on injection, they produce granulation tissue nodules which may resemble tubercles, although on the whole there is a greater tendency to softening and suppuration, and usually the lesions are localised to the site of inoculation. The most important point of distinction is the fact that their multiplication on artificial media is much more rapid, growth usually being visible within forty-eight hours and often within twenty-four hours at 37° C. Furthermore, in most instances growth occurs at the room temperature. The general character of the cultures in this group is a somewhat irregular layer, often with wrinkled surface, dry or moist in appearance, and varying in tint from white to yellow or reddish brown. The number of such organisms is constantly being added to, but the following may be mentioned as examples :—

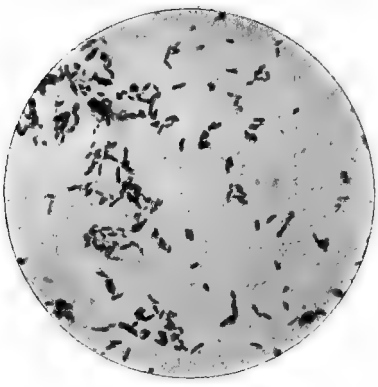

FIG. 81.—Moeller's Timothy-grass bacillus. From a culture on agar. Stained with carbol-fuchsin, and treated with 20 per cent. sulphuric acid. ×1000.

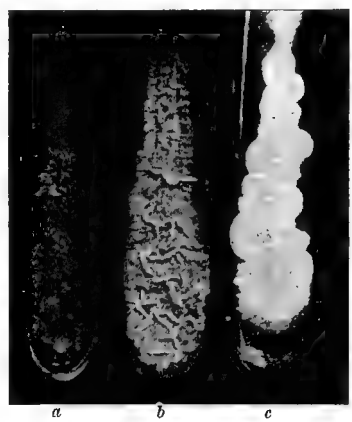
Moeller's Grass Bacilli I. and II.—The former was found in infusions of Timothy-grass (*Phleum pratense*). It is extremely acid-fast, morphologically resembles the tubercle bacillus, and in cultures may show club-formation and branching. The local lesions produced may somewhat resemble tubercles. The colonies, visible in thirty-six hours, are scale-like and of greyish-white colour (Fig. 82, *a*). Moeller's bacillus II. was obtained from the dust of a hay-loft. The colonies at first are moist and somewhat tenacious, but afterwards run together, and are of a dull yellowish colour. The general results of inoculation resemble those of grass bacillus I., but are less marked. Moeller also obtained a similar organism from milk. He also discovered a third acid-fast bacillus, which

he obtained from manure and therefore called the "Mistbacillus" (dung bacillus). This organism has analogous characters, though presenting minor differences. It also produces pathogenic effects.

Petri and Rabinowitch independently cultivated an acid-fast bacillus from butter ("butter bacillus"), in which it occurs with comparative frequency. The organism resembles the tubercle bacillus, although it is on the whole shorter and thicker. Its lesions closely resemble tuberculosis, especially when injection of the organism is made into the peritoneal cavity of guinea-pigs, along with butter,—the method usually adopted in searching for tubercle bacilli in butter. This organism produces pretty rapidly a wrinkled growth (Fig. 82, *b*) not unlike that of Moeller's grass bacillus II. Korn has also obtained other two bacilli from butter which he holds to be distinct from one another and from Rabinowitch's bacillus. The points of distinction are of a minor character. Other more or less similar bacilli have been cultivated by Tobler, Coggi, and others.[1]



a *b* *c*

FIG. 82.—Cultures of acid-fast bacilli grown at room temperature.

(*a*) Moeller's Timothy-grass bacillus I.
(*b*) The Petri-Rabinowitch butter bacillus.
(*c*) Bacillus of fish tuberculosis.

Another bacillus of considerable interest is Johne's bacillus or the bacillus of "chronic bovine pseudo-tuberculous enteritis," the lesions produced by it being corrugated thickenings of the mucous membrane, especially of the small intestine. The disease has now been observed in various countries, and has been found to be comparatively common in Britain. The bacilli occur in large numbers in the lesions, the cells being often packed within them, and can readily be found in scrapings from the surface. They resemble the tubercle bacillus in appearance, but are distinctly shorter; they are equally acid-fast. The organism has been cultivated by Twort and Ingram on egg medium to which there is added ½–1 per cent. of dried and powdered acid-fast bacilli, the Timothy-grass bacillus being most suitable; growth is slow, the colonies appearing after about four weeks in the primary cultures.

Smegma Bacillus.—This organism is of importance, as in form and staining reaction it somewhat resembles the tubercle bacillus and may be mistaken for it. It occurs often in large numbers in the smegma præputiale and in the region of the external genitals, especially where there is an accumulation of fatty matter from the secretions. Morphologically it is a slender, slightly curved organism, like the tubercle bacillus, but usually distinctly shorter (Fig. 83). Like the tubercle bacillus, it stains

[1] For further details on this subject, *vide* Potet, *Études sur les bacilles dites acidophiles*. Paris, 1902.

with some difficulty and resists decolorisation with strong mineral acids. Most observers ascribe the latter fact to the fatty matter with which it is surrounded, and find that if the specimen is treated with alcohol the organism is easily decolorised. Czaplewski, however, who has cultivated it on various media, finds that in culture it shows resistance to decolorisation both with alcohol and with acids, and considers, therefore, that the reaction is not due to the surrounding fatty medium. We have found that in smegma it can be readily decolorised by a minute's exposure to alcohol after the usual treatment with sulphuric acid, and thus it can be readily distinguished from the tubercle bacillus. We, moreover, believe that minor points of difference in the microscopic appearances of the two organisms are quite sufficient to make the experienced observer suspicious if he should meet with the smegma bacillus in urine, and lead him to apply the decolorising test. Difficulty will only occur when a few scattered bacilli retaining the fuchsin are found.

FIG. 83.—Smegma bacilli. Film preparation of smegma. Ziehl-Neelsen stain. ×1000.

Its cultivation, which is attended with some difficulty, was first effected by Czaplewski. On serum it grows in the form of yellowish-grey, irregularly rounded colonies about 1 mm. in diameter, sometimes becoming confluent to form a comparatively thick layer. He found that it also grew on glycerin agar and in bouillon. It is non-pathogenic to various animals which have been tested, unless very large doses are used.

Cowie has found that acid-fast bacilli are of common occurrence in the secretions of the external genitals, mammæ, etc., in certain of the lower animals, and that these organisms vary in appearance. He considers that the term "smegma bacillus" probably represents a number of allied species.

The question may be asked—Do these results modify the validity of the staining reaction of tubercle bacilli as a means of diagnosis? The source of any acid-fast bacilli in question is manifestly of importance, and it may be stated that when these have been obtained from some source outside the body, or where contamination from without has been possible, their recognition as tubercle bacilli cannot be established by microscopic examination alone. In the case of material coming from the interior of the body, however,—sputum, etc.,—the condition must be looked on as different, and although an acid-fast bacillus (not tubercle)

has been found by Rabinowitch in a case of pulmonary gangrene, we have no sufficient data for saying that acid-fast bacilli other than the tubercle bacillus flourish within the tissues of the *human* body, except in such rare instances as to be practically negligible. (To this statement the case of the leprosy bacillus is of course an exception.) Accordingly, up till now, the microscopic examination of sputum, etc., cannot be said to have its validity shaken, and we have the results of enormous clinical experience that such examination is of practically unvarying value. Nevertheless, the facts established with regard to other acid-fast bacilli must be kept carefully in view, and great care must be exercised when only one or two bacilli are found, especially if they deviate in their morphological characters from the tubercle bacillus. In such cases inoculation may be the only reliable test.

Action of dead Tubercle Bacilli.—The remarkable fact has been established by independent investigators, that tubercle bacilli in the dead condition, when introduced into the tissues in sufficient numbers, can produce tubercle-like nodules. Prudden and Hodenpyl, by intravenous injection in rabbits of cultures sterilised by heat, produced in the lungs small nodules in which giant-cells, but no caseation, were occasionally present, and which were characterised by more growth of fibrous tissue than in ordinary tubercle. The subject was very fully investigated with confirmatory results by Straus and Gamaleia, who found that, if the number of bacilli introduced into the circulation were large, there resulted very numerous tubercle nodules with well-formed giant-cells, and occasionally traces of caseation. The bacilli can be well recognised in the nodules by the ordinary staining method. Similar nodules can be produced by intraperitoneal injection. Subcutaneous injection, on the other hand, produces a local abscess, but in this case no secondary tubercles are found in the internal organs. Further, in many of the animals inoculated by the various methods, a condition of marasmus sets in and gradually leads to a fatal result, there being great emaciation before death. These experiments, which have been confirmed by other observers, show that even after the bacilli are dead they preserve their staining reactions in the tissues for a long time, and also that there are apparently contained in the bodies of the dead bacilli certain substances which act locally, producing proliferative and, to a less extent, degenerative changes, and which also markedly affect the general nutrition. S. Stockman has found that an animal inoculated with large numbers of dead tubercle bacilli afterwards gives the tuberculin reaction.

Practical Conclusions.—From the facts above stated with regard to the conditions of growth of the tubercle bacilli, their powers of resistance, and the paths by which they can enter the body and produce disease (as shown by experiment), the manner by which tuberculosis is naturally transmitted can be readily understood. Though the experiments of Sander show that tubercle bacilli can multiply on vegetable media to a certain

extent at warm summer temperature, it is doubtful whether all the conditions necessary for growth are provided to any extent in nature. At any rate, the great multiplying ground of tubercle bacilli is the animal body, and tubercular tissues and secretions containing the bacilli are the chief, if not the only, means by which the disease is spread. The tubercle bacilli leave the body in large numbers in the sputum of phthisical patients, and when the sputum becomes dried and pulverised they are set free in the air. As examples of the extent to which this takes place, it may be said that their presence in the air of rooms containing phthisical patients has been repeatedly demonstrated. Williams placed glass plates covered with glycerin in the ventilating shaft of the Brompton Hospital, and after five days found, by microscopic examination, tubercle bacilli on the surface, whilst Klein found that guinea-pigs kept in the ventilating shaft became tubercular. Cornet produced tuberculosis in rabbits by inoculating them with dust collected from the walls of a consumptive ward. Tubercle bacilli are also discharged in considerable quantities in the urine in tubercular disease of the urinary tract, and also by the bowel when there is tubercular ulceration; but, so far as the human subject is concerned, the great means of disseminating the bacilli in the outer world is dried phthisical sputum, and the source of danger from this means can scarcely be overestimated. Every phthisical patient ought to be looked upon as a fruitful source of infection to those around, and should only expectorate on pieces of rag which are afterwards to be burnt, or into special receptacles which are then to be sterilised either by boiling or by the addition of a 5 per cent. solution of carbolic acid.

Another great source of infection is the milk of cows affected with tuberculosis of the udder, and this is responsible for a considerable proportion of tuberculosis of lymphatic glands, bones, and joints, etc., in young children, as above detailed. In the examination of milk, animal inoculation with centrifugalised samples is the only reliable means of detecting the presence of tubercle bacilli. As pointed out by Woodhead and others, the milk from cows thus affected is probably the great source of tabes mesenterica, which is so common in young subjects (*vide* p. 281). In these cases there may be tubercular ulceration of the intestine, or it may be absent. It is especially in children that this mode of infection occurs, as in the adult ulceration of the intestine is rare as a primary infection, though it is common in phthisical patients as the result of infection by the bacilli in the sputum which has been swallowed. There is

less risk of infection by means of the flesh of tubercular animals, for, in the first place, tuberculosis of the muscles of oxen being very rare, there is little chance of the bacilli being present in the flesh unless the surface has been smeared with the juice of the tubercular organs, as in the process of cutting up the parts; and, in the second place, even when present they will be destroyed if the meat is thoroughly cooked.

We may state, therefore, that the two great modes of infection are by inhalation, and by ingestion, of tubercle bacilli. In the former, the tubercle bacilli will in most cases be derived from the human subject; in the latter, probably from tubercular cows, though inhaled tubercle bacilli may also be swallowed and contamination of food by tubercular material from the human subject may occur. Alike when inhaled and when ingested, tubercle bacilli may lodge about the pharynx and thus come to infect the pharyngeal lymphoid tissue, tonsils, etc., tubercular lesions of these parts being much more frequent than was formerly supposed. Thence the cervical lymphatic glands may become infected, and afterwards other groups of glands, bones, or joints, and internal organs.

The Specific Reactions of Tubercle Bacilli.—The tubercle bacillus belongs to the group of organisms which do not to any extent secrete soluble toxins, but which nevertheless produce effects in the body at a distance from the site of actual proliferation. The origin of these effects is obscure, but there is abundant evidence that, while the injection of dead bacilli tends to produce local lesions, the introduction of the disintegrated protoplasm of the bacillus can produce pathogenic effects of a toxic character. Such disintegrated products (which may be looked on as endotoxins), artificially prepared, were introduced by Koch under the name of tuberculins, and the following are the chief forms in use:—

(1) *Koch's Old Tuberculin.*—This consists of a six-weeks'-old culture of tubercle bacilli in 5 per cent. glycerin bouillon, evaporated down to a tenth of its original volume, killed by heat, and filtered. It thus contains the products of macerated bacilli, substances (not destroyed by heat) formed from the medium during the growth of the organism or extracted from the bacilli by the glycerin,—and the remains of the medium.

(2) *Tuberculin-O.*—Masses of living bacillary growth from surface cultures on agar are dried *in vacuo*, ground in an agate mill, treated with distilled water and centrifugalised; the supernatant clear fluid is the tuberculin. As it gave no cloudiness on the adddition of glycerin, Koch concluded that it contained the glycerin soluble products present in the "old tuberculin" and which were looked on as responsible for the necrotic effects produced by the latter (*vide infra*).

(3) *Tuberculin-R.*—The deposit in the preparation of tuberculin-O is

again ground up in distilled water, centrifugalised, and the clear fluid set aside; the process is again and again repeated with the residue until, on centrifuging, none is left. The successive supernatant fluids are mixed and concentrated, and constitute the tuberculin. As this fluid gives a cloudiness with glycerin, Koch considered it contained the glycerin-insoluble constituents of the "old tuberculin."

(4) *Koch's New Tuberculin* (*Bazillenemulsion*).—A bacillary mass is dried and ground in 50 per cent. glycerin in water till a clear fluid results. This tuberculin is thus equivalent to a mixture of tuberculin-O and tuberculin-R.

(5) *Tuberculin Béraneck.*—This preparation is an extract of tubercle bacilli with 1 per cent. phosphoric acid, the effect of which is supposed to be to destroy some of the more harmful constituents.

A number of other tuberculin preparations have been used, but the above are the most important.

The original tuberculin was introduced by Koch for the treatment of local tuberculous infections. The supposed rationale was that when the artificially produced toxins were injected into the body their action, added to that of the bacilli growing in the focus of infection, caused a sudden exacerbation of the necrotic effect occurring around the bacilli, which resulted in ulceration, whereby the living bacilli were thrown off. It has been found that the injection of the tuberculin directly into the tubercular focus is often not followed by a tuberculin reaction, and although there are other factors to be taken into account this militates against the view that a local concentration of toxin is a sufficient explanation of the phenomenon. The tuberculins are now used for the purposes of diagnosis and to originate immunisation. Their action is extremely complicated and not yet clearly understood, and may be considered under the headings of the production of supersensitiveness, and immunity phenomena.

(1) **Phenomena of Supersensitiveness.**—(*a*) *The Original Tuberculin Reaction.*—This can be manifested with any of the tuberculin preparations. Thus, if ·25 c.c. of "old" tuberculin be hypodermically injected into a healthy individual, there occur in three or four hours malaise, tendency to cough, laboured breathing and moderate pyrexia, all passing off in about twenty-four hours. If, however, only 0·01 c.c. be injected into a tubercular subject, similar symptoms but in a much more aggravated form (the so-called *tuberculin reaction*) arise, and if there be present a local tubercular focus—*e.g.*, lupus—there occurs round it a definite inflammatory reaction with, it may be, ulceration. Similar phenomena of "supersensitiveness" are produced by the injection of almost any foreign proteid into an animal. The subject will be discussed in the chapter on Immunity under the

heading of Anaphylaxis, and it may be said that anaphylaxis is observed when living or dead tubercle bacilli are injected into healthy animals. The tuberculin reaction is much used in diagnosis and, in addition to the methods just described, the following special modifications are frequently used for this purpose :—

(*b*) *The Cutaneous Tuberculin Reaction of von Pirquet and the Ophthalmo-reaction of Calmette.*—In recent times the diagnosis of tuberculosis has been considerably aided by the introduction of these two tests. Both are essentially of the same nature, and depend, like the original tuberculin reaction, on the sensitiveness of the tissues of tubercular patients to tuberculin.

The *cutaneous* test is carried out as follows : The skin, usually that of the flexor aspect of the forearm, is well cleansed with ether and then allowed to dry. Two drops of tuberculin are placed on the prepared surface about four inches apart, and then midway between the two drops a small spot is scarified with a small metal bore constructed for the purpose. This serves as a control, any reaction which follows in it being merely a traumatic one. Similar scarification is effected through the drops of tuberculin, so that the scarified spots are exposed to its action. Small portions of cotton wool are placed over the drops to prevent the tuberculin from running off, and the latter is allowed to act for ten minutes. After that time the cotton wool is removed ; no dressing is required. In the process of scarification only the epidermis should be injured and blood should not be drawn. The "old" tuberculin of Koch is that used. In the case of a positive reaction an inflammatory redness and swelling make their appearance round the sites of tuberculin inoculation, generally within a few hours, and at the end of twenty-four hours there is a distinct inflammatory papule about half an inch in diameter, with a somewhat paler centre like a spot of urticaria ; sometimes in the centre there are minute vesicles. The maximum effect usually occurs within forty-eight hours, and after that time the reaction gradually recedes. Such is the typical reaction, but of course slighter, and also more intense reactions are met with. In a negative reaction all three points of scarification show merely a slight traumatic redness which soon passes off.

For the *ophthalmo-reaction* Calmette uses a purified tuberculin. The tuberculin is prepared as in Koch's original method, and is precipitated with 95 per cent. alcohol ; the precipitate is then dissolved in water. This process is repeated other two times, and the final precipitate is made up as a 1 per cent. solution in distilled water. For use, in the case of an adult, a drop of this

solution is placed in the conjunctival sac and the fluid allowed to spread over the surface; for children about half this quantity is sufficient. In the case of a positive reaction the ocular conjunctiva is congested, the lids become somewhat swollen and their inner surface presents a bright red colour, there is increased secretion of tears and a varying amount of fibrinous exudation. The reaction usually reaches its maximum in from six to ten hours after the instillation, and commences to pass off in from twenty-four to thirty-six hours,—in children a little sooner.

The general results obtained by these two reactions appear to correspond closely. A distinct positive result obtained by either is nearly conclusive as to the presence of a tubercular lesion. In cases of latent tuberculosis the reaction is sometimes obtained, sometimes not. Again, in very advanced cases of tuberculosis, especially a short time before death, a negative result may be got; in some of these cases v. Pirquet has met with a colourless papule or a livid spot without exudation, conditions which he describes as indicating a "cachectic reaction." The ophthalmo-reaction is the more easily applied, at least in adults, but its use is contra-indicated when there is any abnormal condition of the conjunctiva. Even apart from this, however, inflammatory symptoms of disagreeable severity sometimes supervene. It should also be noted that a second test ought not to be applied to the same eye, as the first may produce a condition of super-sensitiveness (p. 290). Von Pirquet claims for his method that in the case of children it can be satisfactorily carried out with greater ease than the ophthalmic test.

It will be recognised that the processes underlying the original tuberculin reaction on the one hand, and the cutaneous and ophthalmic reactions on the other, are analogous. In the former there is the occurrence of local inflammation with metabolic changes and fever; in the latter, of mild inflammatory effects,—in both cases the phenomena being found only in tubercular subjects.

The Use of Old Tuberculin in the Diagnosis of Tuberculosis in Cattle.—In cattle, tuberculosis may be present without giving rise to apparent symptoms. It is thus important from the point of view of human infection that an early diagnosis should be made. The method is applied as follows: The animals are kept twenty-four hours in their stalls, and the temperature is taken every three hours, from four hours before the injection till twenty-four after. The average temperature in cattle is 102·2° F.; 30 to 40 centigrammes of tuberculin are injected, and if the animal be tubercular the temperature rises 2° or 3° F. in eight to twelve hours, and continues elevated for ten to twelve hours. Bang, who has worked most at the subject, lays down the principle that the more nearly the temperature approaches 104° F. the more reason for suspicion

is there. He gives a record of 280 cases where the value of the method was tested by subsequent post-mortem examination. He found that with proper precautions the error was only 3·3 per cent. The method has been largely practised in all parts of the world, and is of great value.

(2) **Immunity Phenomena in Tuberculosis.** — Although recovery from tuberculosis is of frequent occurrence in man, we have at present no clear idea of the processes at work. The object of the therapeutic application of the tuberculins introduced by Koch was to increase the hypothetically existing powers of resistance of the infected individual. The underlying principle was thus the same as in immunisation procedures (*e.g.*, against the typhoid bacillus) with the difference that immunisation was proceeding in an already infected animal. One result has been to stimulate inquiries with a view to observing whether the sera of persons suffering from tuberculosis possess the qualities associated with immunity reactions.

(1) *Immune-bodies and Precipitins.*—Evidence for the existence of the former in tuberculosis has been sought by applying the method of complement fixation (see p. 127), *e.g.*, the serum of a tubercular animal being mixed with tuberculin, the mixture is tested for its capacity of absorbing complement. Following this line, Wassermann and others have found evidence of the presence of an *antituberculin* in tubercular foci. Generally speaking, such an antituberculin is absent from the blood serum of most tubercular patients. In certain cases it may be present in the serum of patients subjected to repeated tuberculin injections. Another immunity phenomenon which may be observed is the formation of a *precipitate* when some of the serum of a tuberculous patient is added to a solution of tuberculin, the mixture being allowed to stand for twenty-four hours (precipitin reaction). There is thus evidence in some tubercular infections of a vital reaction resulting in the formation of antagonistic bodies, which may include both immune-bodies and precipitins. It may be said, however, that the sera of certain animals, *e.g.*, rabbit and ox, when mixed with tuberculin, become capable of deviating complement from a hæmolytic combination.

(2) *Agglutinins.*—The serum of tubercular patients has been found to exert an agglutinating action on the tubercle bacillus. A convenient method is to add different amounts of serum, commencing with, say, 1 c.c., to quantities of a dilution of the new tuberculin (*Bazillenemulsion*) equivalent to 1 part of the bacterial bodies to 10,000 of diluent, and to leave the mixture for twenty-four hours before observing. As with other agglutinative observations, it is difficult to correlate the degree of

agglutinating power of the serum with the degree of immunity possessed by the individual from which it was derived. The method has been used by some as a means of diagnosis, but its value is doubtful and it is certainly inferior to the methods depending on supersensitiveness.

(3) *Opsonins.*—The serum of most normal men and of several species of animals contains opsonins to the tubercle bacillus. In tubercular subjects these are frequently diminished, and to obtain a standard of comparison between infected and healthy subjects samples of serum from a number of persons presenting no signs of tuberculosis are taken and mixed. While the technique of the opsonic method presents great difficulties, it may be taken that with the use of such a standard an opsonic index below ·8 indicates a deficiency in opsonins and an index above 1·2 indicates an excess. In strictly localised tuberculosis, indices from ·1 to ·8 are frequently found, while in tuberculosis with general disturbance the index fluctuates greatly from day to day, being sometimes below, sometimes above unity.

While there is thus evidence that, when the tubercle bacillus gains entrance into the body, reactions similar in nature to those observed in other infections are developed, the processes underlying recovery from tuberculosis are exceedingly obscure, and certain factors have to be taken into consideration which perhaps play a greater part in this disease than in other infections. One of these is the great chronicity so often observed. It is possible that in many cases this is due to wide variations in individual susceptibility and to differences in susceptibility at different age periods. Thus on the whole the most acute cases of tuberculosis are found in childhood. In view of the widespread opportunities for infection which occur, especially in city life, it is probable that the great mass of the adult population is on the border line between complete resistance and a susceptibility of varying degree. On the other hand, there is some evidence that variations exist in the virulence of different strains of the tubercle bacilli. As has been pointed out, it is probable that the bovine variety is less pathogenic for man than the human, but it is probable that even amongst human strains variations in virulence occur, as has recently been insisted upon by Burnet. It has been supposed by many that a cause of insusceptibility in the adult is found in the fact that infection has previously occurred in childhood whereby an immunity is established. The evidence for this at present is rather of an academic nature, and it is certainly extremely difficult to immunise animals against infection with virulent bacilli. It

may be said that the relation of the phenomena of supersensitiveness to those of the development of immunity is at present very obscure.

Therapeutic Applications of the Tuberculins.—As has been indicated, the injection of tuberculins into an infected subject may cause necrosis in a focus of infection, and it was originally supposed by Koch (1890–91) that the origination of such a necrosis might free the body of the invading bacilli. It was soon shown, however, that many single bacilli penetrating the tissues around the focus were left unaffected, and this method of treatment was therefore abandoned.

Tuberculin-R was introduced by Koch in 1897 as a toxin having a minimum of necrotic effect, and the object of its use was to increase the natural powers of resistance of the tubercular subject. Doses commencing with $\frac{1}{4000}$ to $\frac{1}{6000}$ mgrm., gradually increased, were given every second day, the rule laid down for the regulation of the dosage being that no amount should be administered which raised the patient's temperature more than ·5° F. In such doses profound local and general effects were, however, still produced and these were sometimes of a harmful character. The difficulty of controlling the effects militated against the general use of this tuberculin as a curative agent, and it was thus not until Wright investigated the effects of extremely minute doses of the agent that it again came into prominence for therapeutic purposes. At the present time the tendency is to abandon the attempt to assign to different elements in a tuberculin the reactive effects on the one hand and the immunising effects on the other; thus the bacillary emulsion tuberculin is probably as much used as the tuberculin-R, and the object is now to practice such a dosage as shall give the maximum of good effect. For ordinary cases with little or no evidence of constitutional disturbance, an amount of tuberculin corresponding to from a six-hundredth to a one-thousandth of a milligramme of tubercle powder is a sufficient dose; for more marked cases with little or no fever, from a two-thousandth to a four-thousandth of a milligramme is given. In febrile cases the greatest care must be exercised, and a twenty-thousandth to a fifty-thousandth of a milligramme probably represents the limits of safe dosage. The injections are also now given less frequently, usually at ten-day intervals. The best results are obtained where the tuberculous infection is localised, *e.g.*, in lupus, tubercular joints and glands, genito-urinary tuberculosis, and, generally speaking, the dosage must be regulated by a study of the clinical effects. Under certain circumstances information as to the effect of the treatment is easily available. Thus, if in a

quiescent lung affection a tuberculin injection causes increased cough, increase of expectoration, or slight rise of temperature, the dose given has been too large, and the same is true if in a tuberculosis about the bladder symptoms of urinary irritation supervene. While undoubtedly in many cases good results have been obtained, every administration must be looked upon as of the nature of an experiment, and the treatment should only be in the hands of those who have had great experience of the subject.

The fact that in so many cases tubercular infections tend to disappear under ordinary treatment makes it at present extremely difficult to estimate truly the therapeutic effects of vaccine therapy.

Wright holds that the opsonic qualities of the serum constitute the means by which the body frees itself of the invading bacilli. A natural cure results when the absorption into the circulation of the products of the local disintegration of the tubercle bacilli so stimulates some reactive mechanism in the body that sufficient opsonin is produced to cause a phagocytosis of all the tubercle bacilli present. The occurrence of a low opsonic index in chronic local tuberculosis is due to the using up of the opsonins in the focus of infection, and in such a case the general mechanism has not been stimulated to produce a conquering amount of opsonin. The object of a vaccination is thus to supply this deficiency. If it is successful, the focus is flooded with lymph rich in opsonin and the bacilli are consequently phagocyted and destroyed. The reaction of the opsonin-producing mechanism is, however, not a simple one, and as in the introduction of other antigens, the injection of tuberculin is followed by a period, normally lasting a day or two, when the amount of opsonin is actually lower than it previously was (occurrence of negative phase). This, in a successful vaccination, is followed by a rise in opsonic content of the serum to a point above the level existent at the time of injection (production of positive phase). In certain cases a positive phase is easily obtained ; in other cases there is a tendency to a prolonged persistence of the negative phase, and if during such an occurrence a fresh tuberculin injection be produced, a still greater fall in opsonic content may occur, usually accompanied b clinical exacerbation of the tubercular symptoms. Immunisation is further complicated by the fact that there is a variable and often uncontrollable absorption into the body from the focus of infection of what is really tuberculin derived from the disintegration of the infecting bacilli.

Antitubercular Sera.—From what has been said regarding immunity reactions in tuberculosis it will be gathered that it is questionable whether the use of passive immunity in the treatment of tuberculosis has a rational basis. Several investigators, however, have introduced the sera of animals treated with the products of tubercle bacilli for therapeutic purposes. Amongst these are Maragliano, who has treated dogs, asses, and horses with materials derived from the tubercle bacillus, and administers their serum in doses of 2 c.c. every two days in human tuberculosis. An antitubercular sera has also been introduced by Marmorek, who grows the bacilli in media unfavourable to their vitality and employs such growths

for immunising animals whose serum he states is suitable for the treatment of human cases.

Methods of Examination.—(1) *Microscopic Examination.*—Tuberculosis is one of the comparatively few diseases in which a diagnosis can usually be definitely made by microscopic examination alone. In the case of sputum, one of the yellowish fragments which are often present ought to be selected; dried films are then prepared in the usual way, and stained by the Ziehl-Neelsen stain (p. 105). In the case of urine or other fluids, a deposit should first be obtained by centrifuging a quantity in a test-tube, or by allowing the fluids to stand in a tall glass vessel (an ordinary burette is very convenient). Film preparations are then made with the deposit and treated as before. If a negative result is obtained in a suspected case, repeated examination should be undertaken. To avoid risk of contamination with the smegma bacillus, the meatus of the urethra should be cleansed and the urine first passed should be rejected, or the urine may be drawn off with a sterile catheter. As stated above, it is only exceptionally that difficulty will arise to the experienced observer from this cause. (For points to be attended to, *vide* p. 286.) The detection of tubercle bacilli by microscopical methods in sputum, pus, fæces, and even tissues, has been greatly facilitated by the introduction of a preparation called "antiformin." This is a mixture of equal parts of liquor sodæ chlorinatæ (B.P.) and of a 15 per cent. solution of caustic soda. It has a remarkable disintegrative and dissolving action on the tissues, etc., so that after it has been allowed to act on sputum, for example, and the mixture is centrifuged, the resulting deposit is scanty and the tubercle bacilli, if present, are accordingly greatly concentrated. The time necessary may be judged of by the appearance of the mixture, but it will generally be found that the desired result will be obtained after about an hour if one part of sputum be added to two or three parts of 20 per cent. antiformin; the mixture should be shaken from time to time, especially when the sputum is tenacious.

(2) *Inoculation.*—The guinea-pig is the most suitable animal. If the material to be tested is a fluid, it is injected subcutaneously or into the peritoneum; if solid or semi-solid, it is placed in a small pocket in the skin, or it may be thoroughly broken up in sterile water or other fluid and the emulsion injected. By this method, material in which no tubercle bacilli can be found microscopically may sometimes be shown to be tubercular.

(3) *Cultivation.*—The best method to obtain pure cultures is to produce tuberculosis in a guinea-pig by inoculation with tubercular material, and then, killing the animal after four or five weeks, to inoculate tubes of solidified blood serum or egg medium, under strict aseptic precautions, with portions of a tubercular organ, *e.g.*, the spleen. The portions of tissue should be fairly large, and should be well rubbed into the broken surface of the medium. Cultures may, however, be obtained from sputum by means of antiformin, as this substance readily kills most of the ordinary bacteria and has comparatively slight effect on the tubercle bacillus. Antiformin should be allowed to act on sputum in the proportion and for the time mentioned in paragraph (1), the mixture should then be centrifuged, the supernatant fluid removed, and the deposit washed with sterile water and again centrifuged, these processes being repeated several times. If, then, inoculations be made from the deposit on blood serum or on Dorset's egg medium and glycerin egg medium, pure cultures of the tubercle bacillus may, in some instances, be obtained. The method is one which gives good results.

Petroff's method is also recommended as giving satisfactory results. In this, sputum is shaken with an equal volume of 3 per cent. caustic soda solution, and the mixture is placed for half an hour in the incubator at 37° C. At the end of this time it is made neutral to litmus with hydrochloric acid and then centrifuged. Some of the deposit thus obtained is then planted on egg medium to which gentian violet has been added in the proportion of 1 : 10,000, the dye having an inhibitory action on the growth of various organisms. A pure culture of the tubercle bacillus is often obtained.

Another method is that introduced by Twort; portions of sputum are exposed to the action of a 2 per cent. solution of ericolin (a glucoside) for an hour at 38° C., and thereafter cultures are made on Dorset's medium.

(4) *Reactive phenomena.*—The presence of immune-substances in the blood and the tuberculin reaction, along with the methods of applying the respective tests, have been described above (p. 293).

CHAPTER XI.

LEPROSY.

LEPROSY is a disease of great interest, alike in its clinical and pathological aspects; whilst from the bacteriological point of view, also, it presents some striking peculiarities. The disease has a very wide geographical distribution. It occurs in certain parts of Europe—Norway, Russia, Greece, etc., but is commonest in Asia, occurring in Syria, Persia, etc. It is prevalent in Africa, being especially found along the coast, in the Pacific Islands, in the warmer parts of North and South America, and also to a small extent in the northern part of North America. In all these various regions the disease presents the same general features, and the study of its pathological and bacteriological characters, wherever such has been carried on, has yielded similar results.

Pathological Changes.—Leprosy is essentially a chronic disease, in which there is a great amount of tissue change, with comparatively little necessary impairment of the general health. In other words, the local effects of the bacilli are well marked, often extreme, whilst the toxic phenomena are proportionately at a minimum.

There are two chief forms of leprosy. The one, usually called the tubercular form,—*lepra tuberosa* or *tuberculosa*,—is characterised by the growth of granulation tissue in a nodular form or as a diffuse infiltration in the skin, in mucous membranes, etc., great disfigurement often resulting. In the other form, the anæsthetic,—maculo-anæsthetic of Hansen and Looft,—the outstanding changes are in the nerves, with consequent anæsthesia, paralysis of muscles, and trophic disturbances.

In the *tubercular* form, the disease usually starts with the appearance of erythematous patches attended by a small amount of fever, and these are followed by the development of small nodular thickenings in the skin, especially of the face, of the backs of hands and feet, and of the extensor aspects of arms and

legs. These nodules enlarge and produce great distortion of the surface, so that, in the case of the face, an appearance is produced which has been described as "leonine." The thickenings occur chiefly in the cutis (Fig. 84), to a less extent in the subcutaneous tissue. The epithelium often becomes stretched over them, and an oozing surface becomes developed, or actual ulceration may occur. The cornea and other parts of the eye, the mucous

Paraffin section; Ziehl-Neelsen stain. ×80.

membrane of the mouth, larynx, and pharynx, may be the seat of similar nodular growths. Internal organs, especially the spleen, liver, and testicles, may become secondarily affected. In all situations the change is of the same nature, consisting in an abundant formation of granulation tissue, nodular or diffuse in its arrangement. In this tissue a large proportion of the cells are of rounded or oval shape, like hyaline leucocytes; a number of these may be of comparatively large size, and may show vacuolation of their protoplasm and a vesicular type of nucleus. These are often known as "lepra-cells." Amongst the cellular

elements there is a varying amount of stroma, which in the earlier lesions is scanty and delicate, but in the older lesions may be very dense. Periarteritis is a common change, and very frequently the superficial nerves become involved in the nodules, and undergo atrophy. The tissue in the leprous lesions is comparatively vascular, at least when young, and, unlike tubercular lesions, never shows caseation. Some of the lepra cells may contain several nuclei, but we do not meet with cells resembling in their appearance tubercle giant-cells, nor does a focal arrangement like that in tubercle follicles occur.

In the *anæsthetic* form, the lesion of the nerves is the outstanding feature. These are the seat of diffuse infiltrations, which lead to the destruction of the nerve fibres. In the earlier stages, in which the chief symptoms are pains along the nerves, there occur patches on the skin, often of considerable size, the margins of which show a somewhat livid congestion. Later, these patches become pale in the central parts, and the periphery becomes pigmented. There then follows a remarkable series of trophic disturbances, in which the skin, muscles, and bones are especially involved. The skin often becomes atrophied, parchment-like, and anæsthetic; frequently pemphigoid bullæ or other skin eruptions occur. Partly owing to injury to which the feet and hands are liable from their anæsthetic condition, and partly owing to trophic disturbances, necrosis and separation of parts are liable to occur. In this way great distortion results. The lesions in the nerves are of the same nature as those described above, but the granulation tissue is scantier, and has a greater tendency to undergo cicatricial contraction. This is to be associated with the fact that the bacilli are present in fewer numbers.

Bacillus of Leprosy.—This bacillus was first observed in leprous tissues by Hansen in 1871, and was the subject of several communications by him in 1874 and later. Further researches, first by Neisser in 1879, and afterwards by observers in various parts of the world, agreed in their main results, and confirmed the accuracy of Hansen's observations. The bacilli, as seen in scrapings of ulcerated leprous nodules, or in sections, have the following characters: They are thin rods of practically the same size as tubercle bacilli, which they also resemble both in appearance and in staining reaction. They are straight or slightly curved, and usually occur singly, or two may be attached end to end; but they do not form chains. When stained they may have a uniform appearance, or the protoplasm may be fragmented, so that they appear like short rows of cocci. They

often appear tapered at one or both extremities; occasionally there is slight club-like swelling. Degenerated and partially broken-down forms are also seen. They take up the basic aniline stains more readily than tubercle bacilli, but in order to stain them deeply, a powerful stain, such as carbol-fuchsin, is necessary. When stained, they strongly resist decolorising, though they are more easily decolorised than tubercle bacilli

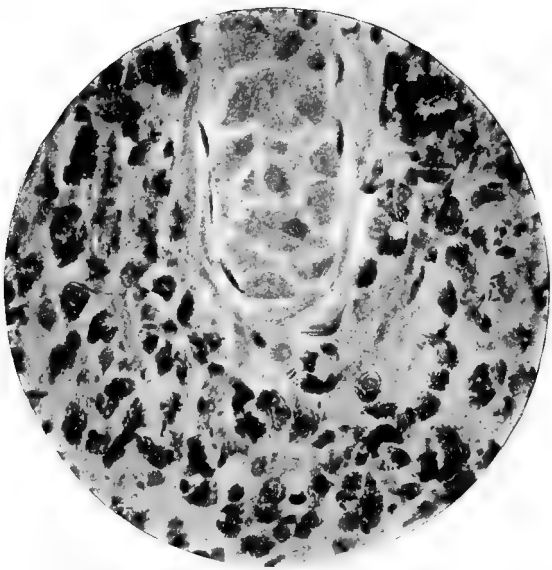

FIG. 85.—Superficial part of leprous skin; the cells of the granulation tissue appear as dark patches, owing to the deeply stained bacilli in their interior. In the upper part a process of epithelium is seen. Paraffin section; stained with carbol-fuchsin and Bismarck-brown. ×500.

(p. 105); variations, however, exist in this respect, some bacilli losing the stain more readily than others. The bacilli are also readily stained by Gram's method. Regarding the presence of spores, practically nothing is known, though some of the unstained or stained points may be of this nature. We have, however, no means of testing their powers of resistance. Leprosy bacilli are non-motile.

Position of the Bacilli.—They occur in enormous numbers in the leprous lesions, especially in the tubercular form—in fact,

so numerous are they that the granulation tissue in sections, properly stained as above, presents quite a red colour under a low power of the microscope (Plate II., Fig. 8). The bacilli occur for the most part within the protoplasm of the round cells of the granulation tissue, and are often so numerous that the structure of the cells is quite obscured (Fig. 85). They are often arranged in bundles which contain several bacilli

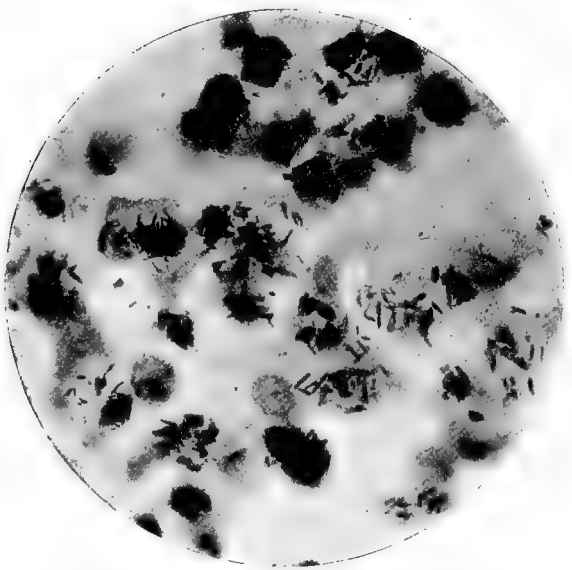

FIG. 86.—High-power view of portion of leprous nodule, showing the arrangement of the bacilli within the cells of the granulation tissue. Paraffin section; stained with carbol-fuchsin and methylene-blue. ×1100.

lying parallel to one another, though the bundles lie in various directions (Fig. 86 and Plate II., Fig. 9). The appearance thus presented by the cells filled with bacilli is very characteristic. Bacilli are also found free in the lymphatic spaces, but the greater number are undoubtedly contained within the cells. They are also found in spindle-shaped connective-tissue cells, in endothelial cells, and in the walls of blood vessels. They are for the most part confined to the connective tissue, but a few may be seen in the hair follicles and glands of the skin. Occasionally one or two may be found in the surface epithelium, where they

probably have been carried by leucocytes, but this position is, on the whole, exceptional. They also occur in large numbers in the lymphatic glands associated with the affected parts. In the internal organs,—liver, spleen, etc.,—when leprous lesions are present, the bacilli are also found, though in relatively smaller numbers. In the nerves in the anæsthetic form they are comparatively few, and in the sclerosed parts it may be impossible to find any. There are few also in the skin patches referred to above as occurring in this form of the disease.

Their spread is chiefly by the lymphatics, though distribution by the blood stream also occurs. They are said to have been found in the blood during the presence of fever and the eruption of fresh nodules, and they have also been observed in the blood vessels *post mortem*, chiefly contained within leucocytes. A few may be detected in some cases in various organs which show no structural change, especially in the capillaries. The brain and spinal cord are almost exempt, but in some cases bacilli have been found even within nerve cells.

FIG. 87.—Kedrowski's leprosy bacillus; pure culture on fish agar. Carbol-fuchsin. ×1000.

Cultivation.—Within recent years various observers have claimed to have cultivated the bacillus of leprosy, but there exists considerable discrepancy in the results obtained, and much additional work is still necessary before a definite statement can be made. Kedrowski cultivated an organism which in culture appeared as a non-acid-fast diphtheroid, but which regained the acid-fast character in the tissues of animals. When injected into mice and rats it produced, in a certain proportion of cases, lesions which presented the essential features of human leprosy,

the bacilli occurring in large numbers within rounded cells. This organism grows very slowly and produces an irregular whitish growth of moist appearance closely resembling that of the avian tubercle bacillus. Bayon has confirmed Kedrowski's results. Clegg grew a small acid-fast bacillus on plain agar medium along with amœbæ and symbiotic bacteria, and then by killing the contaminating organisms by means of heat, obtained a pure growth of a chromogenic acid-fast bacillus. Duval following out this work obtained confirmatory results, but in addition to Clegg's bacillus he cultivated a slowly growing non-chromogenic bacillus which only grew on special media (*vide infra*). This latter he believes to be probably the causal organism. He lays stress especially upon its very slow growth, the colonies after 8–10 months being about the size of those of the influenza bacillus, and upon its requiring the presence of the products of protein digestion. Twort also claims to have cultivated the organism on glycerin egg-medium containing dead tubercle bacilli in the proportion of 1 per cent. Rost and Williams have cultivated a pleomorphous organism, a streptothrix, which may appear in the form of bacilli or branched filaments, and both of these forms may be acid-fast or non-acid-fast. Their organism, it is to be noted, however, grows comparatively rapidly, growth being visible within a week, whilst in the case of the organisms of Kedrowski, Duval, and Twort, growth only appears after several weeks. Furthermore, the organisms of Duval and Twort appear only in the bacillary form, whilst those of the other observers mentioned show pleomorphism. Bayon has compared the pathogenic properties of the bacilli cultivated by different workers, and finds that only Kedrowski's bacillus and that cultivated by himself, which he regards as the same organism, produce in animals lesions similar to those of leprosy, the cells in the lesions being stuffed with bacilli, and there appears to be no doubt that in his preparations a multiplication of the organism has taken place. He also finds that only these two strains give a distinct deviation of complement (p. 127) when tested with the serum of leprous patients. It is quite clear that the organisms cultivated by various workers and claimed to be leprosy bacilli present essential differences. At present it is not possible to express any definite opinion on the subject.

For a long time attempts to transmit leprosy to the lower animals were unsuccessful. The only exception to this statement is afforded by the experiments of Melcher and Orthmann, who produced nodules in the organs of rabbits after inoculating the

anterior chamber of the eye with leprous material, the cells in the nodules containing numerous bacilli. These results have been generally called in question, but in view of recent work it is quite possible that the lesions were really of leprous nature. Sugai has found that the Japanese dancing-mouse is comparatively susceptible to inoculation with leprous material and Duval has confirmed this observation. The experiments of Kedrowski and Bayon have already been referred to. It is to be noted, however, that in all these cases success is only obtained in a certain proportion of cases, and also that the picture of cells stuffed with bacilli has also been obtained by the injection of acid-fast saprophytes. It would accordingly be a mistake to place much reliance on this point. Experiments have also been performed on monkeys, but the results cannot be regarded as conclusive.

Media.—Of the various media used by different workers the following may be given as examples. Williams used a fluid medium which is a modification of Rost's original medium, composed of Lemco broth 250 c.c., distilled water 250 c.c., milk 20 c.c. In addition to cultures along with various bacteria, Duval recommends the following: (*a*) 2 parts of 2 per cent. agar of a titre, 1·5 per cent. alkaline to phenol-phthalein, and 1 part of a 2 per cent. solution of tryptophane or cysteine; (*b*) agar, 1 per cent. alkaline, is planted with fragments of leprous tissue and a non-sporing proteolytic bacterium. After ten days or two weeks the culture is exposed to a temperature of 60° C. for half an hour, this being sufficient to kill the hydrolysing bacterium but not the leprosy bacilli. The cultures are then incubated further.

Bayon uses « fish-agar medium, composed of equal parts of a watery extract of fishes' muscle, rendered sterile by filtration, and 4 per cent. ordinary agar.

It is interesting to note that a disease occurs under natural conditions in rats which presents many points of close similarity to leprosy. It is very widespread, having been observed in Europe, Asia, America, and Australia; an excellent description was given by G. Dean. In this affection there are lesions in the skin which resemble those in leprosy, and the cells contain enormous numbers of an acid-fast bacillus. The disease can be transmitted to rats by inoculation with the tissue juices containing the bacilli, but not to animals of other species. The relations of this affection to human leprosy have not yet been worked out, but the facts recently obtained regarding the transmission of leprosy to animals suggest the possibility that the two diseases may be the same; at any rate they are very closely allied. Bayon claims to have cultivated the bacillus of rat leprosy and finds that it is practically identical, as regards

both cultural characters and pathogenic effects, with the organism obtained from the human disease.

Nastin.—This substance has been pretty extensively used in the treatment of leprosy and certain favourable effects have been recorded. It is a crystallisable neutral fat, composed of a high molecular fatty acid and glycerin, and was extracted by Deycke and Reschad by means of ether and alkaline alcohol from an acid-fast streptothrix obtained from a case of leprosy (the relation of this organism to the "bacillus of leprosy" is still doubtful). It is usually given as a mixture with benzoyl chloride and is said to give a specific reaction on injection into lepers. Much considers that "nastin" is a substance common to various acid-fast bacteria and capable of stimulating the formation of anti-substances to these organisms. Wills takes a somewhat similar view, holding that there are definite substances of the fatty group common to acid-fast bacteria which are capable of functioning as antigens. If this view is correct, the occurrence of a reaction on the injection of a given acid-fast organism, or of its products, into a leper will be devoid of specific significance as regards the relation of that organism to the disease.

It would also appear that the disease is not readily inoculable in the human subject. In a well-known case described by Arning, a criminal in the Sandwich Islands was inoculated in several parts of the body with leprosy tissue. Two or three years later, well-marked tubercular leprosy appeared, and led to a fatal result. This experiment, however, is open to the objection that the individual before inoculation had been exposed to infection in a natural way, having been frequently in contact with lepers. In other cases, inoculation experiments on healthy subjects and inoculations in other parts of leprous individuals have given negative results. It has been supposed by some that the failure to obtain cultures and to reproduce the disease experimentally may be partly due to the bacilli in the tissues being dead. The varying results of inoculation of the human subject present, to an extent, a parallel to the results of experiments on animals, as given above.

The facts stated with regard to cultivation and inoculation experiments go to distinguish the leprosy bacillus all the more strongly from other organisms. Some have supposed that leprosy is a form of tubercle, or tubercle modified in some way, but for this there appears to us to be no evidence. It should also be mentioned that tubercle is a not uncommon complication in leprous subjects, in which case it presents the ordinary characters. It has been found that a considerable proportion of lepers react to tuberculin like tubercular patients. This result has been variously interpreted, some considering that tuberculosis is also present in such cases, whilst others maintain that the reaction may be given in the absence of tubercle. If, as is probable, the

latter is the case, the result most likely depends on the close relationship of the organisms of the two diseases; it by no means proves their identity. Another curious fact is that the Wassermann reaction (p. 132) may be given by the serum of leprous patients (in about 50 per cent., according to some observers); this would seem to be quite independent of the concurrent presence of syphilis, but it is not possible at present to give an explanation of the phenomenon.

The mode by which leprosy is transmitted has been the subject of great controversy, and is one on which authorities still hold opposite opinions. Some consider that it is a hereditary disease, or at least that it is transmitted from a parent to the offspring; others, again, that it is transmitted by direct contact. There appears to be no doubt, however, that on the one hand leprous subjects may bear children free from leprosy, and that on the other hand healthy individuals entering a leprous district may contract the disease, though this rarely occurs. Of the latter occurrence there is the well-known instance of Father Damien, who contracted leprosy after going to the Sandwich Islands. In view of all the facts, there can be little doubt that leprosy in certain conditions may be transmitted by direct contact, though its contagiousness is not of a high order. It is not at present possible to make any definite statement as to the transmission of the disease by means of insects.

Methods of Diagnosis.—Film preparations should be made with the discharge from any ulcerated nodule which may be present, or from the scraping of a portion of excised tissue, and should be stained as above described. The presence of large numbers of bacilli situated within the cells and giving the staining reaction of leprosy bacilli, is conclusive. It is more satisfactory, however, to make microscopic sections through a portion of the excised tissue, when the structure of the nodule and the arrangement of the bacilli can be readily studied. The points of difference between leprosy and tubercle have already been stated, and in most cases there is really no difficulty in distinguishing the two conditions. A negative result, on inoculating a guinea-pig with the suspected material, will exclude tuberculosis.

CHAPTER XII.

GLANDERS AND RHINOSCLEROMA.

Glanders.

The bacillus of glanders (bacillus mallei; Fr., *bacille de la morve*; Ger., *Rotzbacillus*) was discovered by Löffler and Schutz, the announcement of this discovery being made towards the end of 1882. They not only obtained pure cultures of this organism from the tissues in the disease, but by experiments on horses and other animals conclusively established its causal relationship. These have been fully confirmed. The same organism has also been cultivated from the disease in the human subject, first by Weichselbaum in 1885, who obtained it from the pustules in a case of acute glanders in a woman, and by inoculation of animals obtained results similar to those of Löffler and Schutz.

Within more recent times a substance, *mallein*, has been obtained from the cultures of the glanders bacillus by a method similar to that by which tuberculin is prepared, and has been found to produce effects in animals suffering from glanders corresponding to those produced by tuberculin in tuberculous animals.

The Natural Disease.—Glanders chiefly affects the equine species—horses, mules, and asses. Horned cattle, on the other hand, are quite immune, whilst goats and sheep occupy an intermediate position, the former being rather more susceptible and occasionally suffering from the natural disease. It also occurs in some of the carnivora—cats, lions and tigers in menageries, which animals are infected from the carcases of animals affected with the disease. Many of the small rodents are highly susceptible to inoculation (*vide infra*).

Glanders is also found in man as the result of direct inoculation of some wound of the skin or other part by means of the discharges or diseased tissues of an animal affected, and hence is commonest amongst grooms and others whose work brings them into contact with horses; even amongst them it is a comparatively rare disease.

In horses the lesions are of two types, to which the names "glanders" proper and "farcy" have been given, though both may exist together. In glanders proper, the septum nasi and adjacent parts are chiefly affected, there occurring in the mucous membrane nodules which are at first firm and of somewhat translucent grey appearance. The growth of these is usually attended by inflammatory swelling and profuse catarrhal discharge. Afterwards the nodules soften in the centre, break down, and give rise to irregular ulcerations. Similar lésions, though in less degree, may be found in the respiratory passages. Associated with these lesions there is usually implication of the lymphatic glands in the neck, mediastinum, etc.; and there may be in the lungs, spleen, liver, etc., nodules of the size of a pea or larger, of greyish or yellow tint, firm or somewhat softened in the centre, and often surrounded by a congested zone. The term "farcy" is applied to the affection of the superficial lymphatic vessels and glands, which is specially seen where infection takes place through an abrasion of the skin, such as is often produced by the rubbing of the harness. The lymphatic vessels become irregularly thickened, so as to appear like knotted cords, and the associated lymphatic glands become enlarged and firm, though suppurative softening usually follows, and there may be ulceration. These thickenings are often spoken of as "farcy buds" and "farcy pipes." In farcy, also, secondary nodules may occur in internal organs and the nasal mucous membrane. The disease is often present in a "latent form," and its presence can only be detected by the mallein test (*vide infra*). In the ass the disease runs a more acute course than in the horse.

In man the disease is met with in two forms, an acute and a chronic—though intermediate forms also occur, and chronic cases may take on the characters of the acute disease. The site of inoculation is usually on the hand or arm,—by means of some scratch or abrasion, or possibly by infection along a hair follicle,—sometimes on the face, and occasionally on the mucous membrane of the mouth, nose, or eye. In the *acute* form there appears at the site of inoculation inflammatory swelling, attended usually with spreading redness, and the lymphatics in relation to the part also become inflamed, the appearances being those of a "poisoned wound." These local changes are soon followed by marked constitutional disturbance, and by a local or widespread eruption on the surface of the body, at first papular and afterwards pustular, and later there may form in the subcutaneous tissue and muscles larger masses which soften and suppurate, the pus being often mixed with blood; suppuration may occur also in the joints. In some cases the nasal mucous membrane may be secondarily infected, and thence inflammatory swelling may spread to the tissues of the face. The patient usually dies in two or three weeks, sometimes sooner, with the symptoms of rapid pyæmia. In addition to the lesions mentioned, there may be foci, usually suppurative, in the lungs (attended often with pneumonic consolidation), in the spleen, liver, bone-marrow,

salivary glands, etc. In the *chronic* form a local granulomatous condition may occur, which usually breaks down and gives rise to the formation of an irregular ulcer with thickened margins, and sanious, often foul, discharge. The ulceration spreads deeply as well as superficially, and the thickened lymphatics also have a great tendency to ulcerate, though the lymphatic system is not so prominently affected as in the horse. Deposits may form in the subcutaneous tissue and muscles, and the mucous membrane may become affected. The disease may run a very chronic course, lasting for months or even years, and recovery may occur; on the other hand, such a case may at any time take on the characters of the acute form of the disease and rapidly become fatal. Even when there is apparent recovery recurrence may occur.

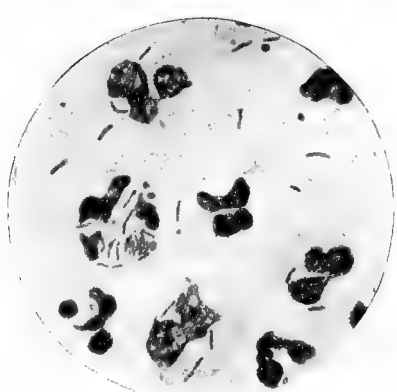

FIG. 88.—Glanders bacilli,—several contained within leucocytes,—from peritoneal exudate in a guinea-pig. Stained with weak carbol-fuchsin. × 1000.

The Glanders Bacillus. — *Microscopical Characters.*—The glanders bacilli are minute rods, straight or slightly curved, with rounded ends, and about the same length as tubercle bacilli, but distinctly thicker (Fig. 88). They show, however, considerable variations in size and in appearance, and their protoplasm is often broken up into a number of deeply-stained portions with unstained intervals between. These characters are seen both in the tissues and in cultures, but, as in the case of many organisms, irregularities in form and size are more pronounced in cultures (Fig. 89); short filamentous forms 8 to 12 μ in length are sometimes met with, but these are on the whole rare. The organism is non-motile and does not form spores.

In the tissues the bacilli usually occur irregularly scattered amongst the cellular elements; a few may be contained within leucocytes and connective-tissue corpuscles, but the position of most is extracellular. They are most abundant in the acute

lesions, in which they may be found in considerable numbers; but in the chronic nodules, especially when softening has taken place, they are few in number, and it may be impossible to find any in sections.

Staining.—The glanders bacillus differs widely from the tubercle bacillus in its staining reactions. It stains with simple watery solutions of the basic stains, but somewhat faintly (better when an alkali or a mordant, such as carbolic acid, is added), and even when deeply stained it readily loses the colour when a decolorising agent such as alcohol is applied. It is Gram-negative. In film preparations from fresh glanders nodules the bacilli can be readily found by staining with any of the ordinary combinations, *e.g.*, carbol-thionin-blue or weak carbol-fuchsin. In the case of sections, we have obtained the best results by carbol-thionin-blue (p. 102), and we prefer to dehydrate by the aniline-oil method.

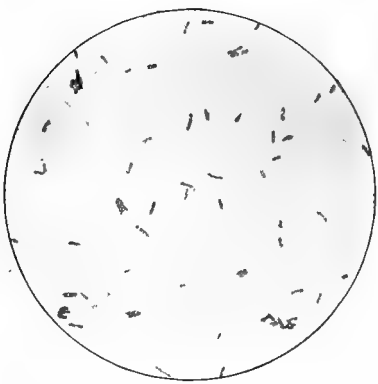

FIG. 89.—Glanders bacilli, from a pure culture on glycerin agar.
Stained with carbol-fuchsin and partially decolorised to show segmentation of protoplasm. × 1000.

McFadyean recommends that after sections have been stained in Löffler's methylene-blue and slightly decolorised in weak acetic acid, they should be treated for fifteen minutes with a saturated solution of tannic acid; thereafter they are washed thoroughly in water, and as a contrast stain a 1 per cent. solution of acid fuchsin may be applied for half a minute; they are then dehydrated, cleared, and mounted.

Cultivation.—(For the methods of separation, *vide infra.*) The glanders bacillus grows readily on most of the ordinary media, but a somewhat high temperature is necessary, growth taking place most rapidly at 35° to 37° C. Though a certain amount of growth occurs down to 21° C., a temperature above 25° C. is always desirable.

On *agar* and *glycerin agar*, in stroke cultures, growth appears along the line as a uniform streak of greyish-white colour and somewhat transparent appearance, with moist-looking surface, and when touched with a needle is found to be of rather slimy

consistence. Later it spreads laterally for some distance, and the layer becomes of slightly brownish tint.

In *bouillon*, growth forms at first a uniform turbidity, but soon settles to the bottom, and after a few days forms a pretty thick flocculent deposit of slimy and somewhat tenacious consistence.

On *serum* the growth is somewhat similar but more transparent, the separate colonies being in the form of round and almost clear drops. In sub-cultures at the body temperature growth is visible within twenty-four hours, but when fresh cultures are made from the tissues it may not be visible till the second day. Serum or potato is much more suitable for cultivating from the tissues than the agar media.

On *potato* at 30°–37° C. the glanders bacillus flourishes well and produces a characteristic appearance, incubation at the higher temperature, however, being advisable. Growth proceeds rapidly, and on the third day has usually formed a transparent layer of slightly yellowish tint, like clear honey in appearance. On subsequent days, the growth still extends and becomes darker in colour and more opaque, till about the eighth day it has a reddish-brown or chocolate tint. The characters of the growth on potato, along with the microscopical appearances, are quite sufficient to distinguish the glanders bacillus from every other known organism (sometimes the cholera organism and the b. pyocyaneus produce a somewhat similar appearance, but they can be readily distinguished by their other characters). Potato is also a suitable medium for starting cultures from the tissues; in this case minute transparent colonies become visible on the third day, and afterwards present the appearances just described.

Powers of Resistance.—The glanders bacillus is not killed at once by drying, but usually loses its vitality after fourteen days in the dry condition, though sometimes it lives longer. It is not quickly destroyed by putrefaction, as it has been found to be still active after remaining two or three weeks in putrefying fluids. It has comparatively feeble resistance to heat and antiseptics. Löffler found that it was killed in ten minutes in a fluid kept at 55° C., and in from two to three minutes by a 5 per cent. solution of carbolic acid.

We may summarise the characters of the glanders bacillus by saying that in its morphological characters it resembles somewhat the tubercle bacillus, but is thicker, and differs widely from it in its staining reactions. For its cultivation the higher temperatures are necessary, and the growth on potato presents most characteristic features.

Experimental Inoculation.—In horses, subcutaneous injection of the glanders bacillus in pure culture reproduces all the important features of the disease. This fact was established at a comparatively early date by Löffler and Schutz, who, after one doubtful experiment, successfully inoculated two horses in this way, the cultures used having been grown for several generations outside the body. All the features of the disease were reproduced. The ass is even more susceptible than the horse, the disease in the former running a more rapid course, but with similar lesions. The ass can be readily infected by simple scarification and inoculation with glanders secretion, etc. (Nocard).

Of small animals, field-mice and guinea-pigs are the most susceptible; on the other hand, house-mice and white mice enjoy an almost complete immunity. In field-mice, subcutaneous inoculation is followed by a very rapid disease, usually leading to death within eight days, the organisms becoming generalised and producing numerous minute nodules, especially in the spleen, lungs, and liver. In the guinea-pig the disease is less acute. At the site of inoculation an inflammatory swelling forms, which soon softens and breaks down, leading to the formation of an irregular crateriform ulcer with indurated margins. The lymphatic vessels become infiltrated, and the corresponding lymphatic glands become enlarged to the size of peas or small nuts, softened, and semi-purulent. The animal sometimes dies in two or three weeks, sometimes not for a longer period. Secondary nodules, in varying numbers in different cases, may be present in the spleen, lungs, bones, nasal mucous membrane, testicles, etc.; in some cases a few nodules are found in the spleen alone. Intraperitoneal injection in the male guinea-pig is followed, as pointed out by Straus, by a very rapid and semi-purulent affection of the tunica vaginalis, shown during life by great swelling and redness of the testicles, which changes may be noticeable in two or three days, or even earlier. This method of inoculation has been found of service for purposes of cultivation and diagnosis. Rabbits are less susceptible than guinea-pigs, and the effect of subcutaneous inoculation is somewhat uncertain. Accidental inoculation of the human subject with pure cultures of the bacillus has in more than one instance been followed by the acute form of the disease and a fatal result.

Mayer has found that when the glanders bacillus is injected along with melted butter into the peritoneum of a guinea-pig, it shows filamentous, branching, and club-shaped forms; in other words, it presents the characters of a streptothrix. Lubarsch, on the other hand,

in a comparative study of the results of inoculation with acid-fast and other bacilli, found none of the above characters in the case of the glanders bacillus.

Action on the Tissues.—The glanders bacillus causes a more rapid and more marked inflammatory reaction than the tubercle bacillus; there is more leucocytic infiltration and less proliferative change. Thus the centre of an early glanders nodule shows a dense aggregation of leucocytes, most of which are polymorphonuclear, whilst in the central parts many show fragmentation of nuclei with the formation of a deeply staining granular detritus. And further, the inflammatory change may be followed by suppurative softening of the tissue, especially in certain situations, such as the subcutaneous tissue and lymphatic glands. The nodules, therefore, in glanders, as Baumgarten put it, occupy an intermediate position between miliary abscesses and tubercles. The diffuse coagulative necrosis and caseation which are so common in tubercle do not occur to the same degree in glanders, and typical giant-cells are not formed. The tendency to spread by the lymphatics is always a well-marked feature, and when the bacilli gain entrance to the blood stream they soon settle in the various tissues and organs. Accordingly, even in acute cases it is usually quite impossible to detect the bacilli in the circulating blood, though sometimes they have been found. It is an interesting fact, shown by observations of the disease both in the human subject and in the horse, as well as by experiments on guinea-pigs, that the mucous membrane of the nose may become infected by means of the blood stream—another example of the tendency of organisms to settle in special sites.

Mode of Spread.—Glanders usually spreads from a diseased animal by direct contagion with the discharge from the nose or from the sores, etc. There is no evidence that the disease is produced in man by inhalation of the bacilli in the dried condition. Some authorities consider that pulmonary glanders may be produced in this way in the horse, whilst others maintain that in all cases there is first a lesion of the nasal mucous membrane or of the skin surface, and that the lung is affected secondarily. Babés, however, found that the disease could be readily produced in susceptible animals by exposing them to an atmosphere in which cultures of the bacillus had been pulverised. He also found that inunction of the skin with vaseline containing the bacilli might produce the disease, the bacilli in this case entering along the hair follicles.

Serum Reactions.—Shortly after the discovery of agglutination in typhoid fever, McFadyean found that the serum of glandered horses possessed the power of agglutinating glanders bacilli. His later observations show that in the great majority of cases of glanders a 1 : 50 dilution of the serum produces marked agglutination in a few minutes, whilst in the great majority of non-glandered animals no effect is produced under these conditions. The test performed in the ordinary way is, however, not absolutely reliable, as exceptions occasionally occur in both directions, *i.e.*, negative results by glandered animals and positive results by non-glandered animals. He found that a more delicate and reliable method is to grow the bacillus in bouillon containing a small proportion of the serum to be tested. In this way he obtained a distinct, sedimenting reaction with a serum which did not agglutinate at all distinctly in the ordinary method. Within recent times the sedimentation test by the ordinary method (p. 117) has been most generally used. The general result seems to be that distinct sedimentation within thirty-six hours with a serum dilution of 1 : 1000 may be taken as a positive result, indicating the presence of glanders ; whilst reactions with dilutions between this and 1 : 500 are highly suspicious but not conclusive. The deviation of complement test (p. 127) is also applicable in the case of glanders, and this has given valuable results in the hands of various observers. Precipitin reactions may also be obtained on the addition of mallein or an extract of the glanders bacillus to the serum of a glandered animal. These reactions, which of course depend on the presence of anti-substance in the blood in glanders, form important auxiliaries to the method of diagnosis by means of mallein.

Mallein and its Preparation.—Mallein is obtained from cultures of the glanders bacillus grown for a suitable length of time, and, like tuberculin, is really a mixture comprising (1) substances in the bodies of the bacilli, and (2) their soluble products, not destroyed by heat, along with substances derived from the medium of growth. It was at first obtained from cultures on solid media by extracting with glycerin or water, but is now usually prepared from cultures in glycerin bouillon. Such a culture, after being allowed to grow for three or four weeks, is sterilised by heat either in the autoclave at 115° C. or by steaming at 100° C. It is then filtered through a Chamberland filter. The filtrate constitutes fluid mallein. Usually a little carbolic acid (·5 per cent) is added to prevent it from decomposing. Of such mallein 1 c.c. is usually the dose for a horse (McFadyean). Foth has prepared a dry form of mallein by throwing the filtrate of a broth culture, evaporated to one-tenth of its bulk, into twenty-five or thirty times its volume of alcohol. A white precipitate is formed, which is dried over calcium chloride and then under an air-pump. A dose of this dry mallein is ·05 to ·07 grm.

The Use of Mallein as a Means of Diagnosis.—In using mallein for the diagnosis of glanders, the temperature of the animal ought to be observed for some hours beforehand, and after subcutaneous injection of a suitable dose, it is taken at definite intervals,—according to McFadyean at the sixth, tenth, fourteenth, and eighteenth hours afterwards, and on the next day. Here both the local reaction and the temperature are of importance. In a glandered animal, at the site of inoculation there is a somewhat tender local swelling, which reaches a diameter of five inches at least, the maximum size not being attained until twenty-four hours afterwards. The temperature rises 1·5° to 2° C., or more, the maximum generally occurring in from eight to sixteen hours. If the temperature

never rises as much as 1·5°, the reaction is considered doubtful. In the negative reaction given by an animal free from glanders, the rise of temperature does not usually exceed 1°, the local swelling reaches the diameter of three inches at most, and has much diminished at the end of twenty-four hours. In the case of dry mallein, local reaction is less marked. Veterinary authorities are practically unanimous as to the great value of the mallein test as a means of diagnosis. It has recently been shown that mallein instilled into the conjunctival sac, or inoculated by scarification into the skin of glandered animals, gives corresponding reactions to the ophthalmic and cutaneous tuberculin reactions in cases of tuberculosis (p. 291); in the case of glanders the conjunctival reaction would appear to be the more convenient and reliable.

Methods of Examination.—Microscopic examination in a case of suspected glanders will at most reveal the presence of bacilli corresponding in their characters to the glanders bacillus. An absolute diagnosis cannot be made by this method. Cultures may be obtained by making successive strokes on blood serum or on potato, and incubating at 37° C. The colonies of the glanders bacillus do not appear till two or three days afterwards. This method may fail unless a considerable number of the glanders bacilli are present. The most certain method, however, is by inoculation of a guinea-pig, either by subcutaneous or intra-peritoneal injection. By the latter method, as above described, lesions are much more rapidly produced, and are more characteristic. If, however, there have been other organisms present, the animal may die of a septic peritonitis, though even in such a case the glanders bacilli will be found to be more numerous in the tunica vaginalis, and may be cultivated from this situation. It is extremely doubtful whether the application of mallein to diagnosis of the disease in the human subject is justifiable. There is a certain risk that it may lead to the lesions assuming a more acute character; moreover, culture and inoculation tests are generally available. In the case of horses, etc., a diagnosis will, however, be much more easily and rapidly effected by means of mallein, or by one of the serum reactions described above. In some cases of acute glanders in the human subject the bacillus has been obtained in cultures from the blood during life.

Rhinoscleroma.

This disease is considered here as, from the anatomical changes, it also belongs to the group of infective granulomata. It is characterised by the occurrence of chronic nodular thickenings in the skin or mucous membrane of the nose, or in the mucous membrane of the pharynx, larynx, or upper part of the trachea. The nodules are of considerable size, sometimes

as large as a pea; in the earlier stages they are comparatively smooth on the surface, but later they become shrunken and the centre is often retracted. The disease is scarcely ever met with in this country, but is of not uncommon occurrence on the Continent, especially in Austria and Poland. In the granulation tissue of the nodules there are to be found numerous round and rather large cells, which have peculiar characters and are often known as the cells of Mikulicz. Their protoplasm contains a collection of somewhat gelatinous material which may fill the cell and push the nucleus to the side. Within these cells there is present a characteristic bacillus, occurring in little clumps or masses, chiefly in the gelatinous material. A few bacilli also lie free in the lymphatic spaces around. This organism was first observed by Frisch, and is now known as the bacillus of rhinoscleroma. The bacilli have the form of short oval rods, which, when lying separately, can be seen to possess a distinct capsule, and which in all their microscopical characters correspond closely with Friedländer's pneumobacillus. They are usually present in the lesions in a state of purity. It was at first stated that they could be stained by Gram's method, but more recent observations show that, like Friedländer's organism, they lose the stain.

From the affected tissues this bacillus can be easily cultivated by the ordinary methods. In the characters of its growth in the various culture media it presents a close similarity to the pneumobacillus, as it also does in its fermentative action in milk and sugar-containing fluids. The nail-like appearance of the growth on gelatin is said to be less distinct, and the growth on potatoes is more transparent and may show small bubbles of gas; but it is doubtful whether any distinct line of difference can be drawn between the two organisms so far as their microscopical and cultural characters are concerned.

The serum of patients suffering from the disease gives fixation of complement when tested with an emulsion of the bacillus, but varying results have been obtained as regards the validity of the test in the differentiation of the bacillus from the allied organisms.

The evidence that the organisms described are the cause of this disease consists in their constant presence and their special relation to the affected tissues, as already described. From these facts alone it would appear probable that they are the active agents in the production of the lesions. Experimental inoculation has thrown little light on the subject, though one observer has described the production of nodules on the conjunctivæ of guinea-pigs. The relation of the rhinoscleroma

organism to that of Friedländer is still a matter of doubt, and the matter has been further complicated by the fact that a bacillus possessing closely similar characters has been found to be very frequently present in ozœna, and is often known as the *bacillus ozœnœ*. The last-mentioned organism is said to have more active fermentative powers. From what has been stated it will be seen that a number of organisms, closely allied in their morphological characters, have been found in the nasal cavity in healthy or diseased conditions. There is no doubt that rhinoscleroma is a specific disease with well-marked characters, and it is quite possible that one member of this group of organisms may be the causal agent, though indistinguishable from others by culture tests. There is, however, a tendency on the part of recent investigators, *e.g.*, Perkins, to consider the "bacillus of rhinoscleroma" to be identical with the pneumo-bacillus, and its presence in the affected tissues to represent merely a secondary invasion. The subject is one on which more light is still required.

CHAPTER XIII.

ACTINOMYCOSIS AND ALLIED DISEASES.

Actinomycosis is the most important of the group of diseases produced by organisms of the genus *streptothrix* (Cohn) or *discomyces* (Rivolta and French writers). It occurs in man in common with certain of the domestic animals, though it is more frequent in the latter, especially in oxen, swine, and horses. The parasite was first discovered in the ox by Bollinger, and described by him in 1877, the name *actinomyces* or *ray fungus* being from its appearance applied to it by the botanist Harz. In 1878 Israel described the parasite in the human subject, and in the following year Ponfick identified it as being the same as that found in the ox. It is, however, to be noted that the term "actinomyces," as originally used, does not represent one parasite but a number of allied species, as cultures obtained from various sources have presented considerable differences. Moreover, it has been found by Lignières and Spitz that in a common type of actinomycosis in the ox the colonies are formed not by a streptothrix but by a bacillus to which they have given the name of *actinobacillus*. The term "actinomycosis" accordingly does not represent a specific disease, but may conveniently be retained for infections in which the parasite forms "granules" or colonies with a more or less radiate appearance at the periphery. Such infections have now been shown to be of comparatively common occurrence. Further, other distinct species of streptothrix, without the characteristic arrangement, have been cultivated from isolated cases of disease in the human subject where the lesions resembled more or less closely those of actinomycosis. In one or two instances the organism has been found to be "acid-fast," and there is no doubt that the actinomyces group is closely related through intermediate forms with the tubercle group (*vide* p. 269).

Naked-Eye Characters of the Parasites.—The actinomyces grow in the tissues in the form of little round masses or colonies,

which, when fully developed, are easily visible to the naked eye, the largest being about the size of a small pin's head, whilst all sizes below this may be found. When suppuration is present, they lie free in the pus; when there is no suppuration, they are embedded in the granulation tissue, but are usually surrounded by a zone of softer tissue. They may be transparent or jelly-like, or they may be opaque and of various colours—white, yellow, greenish, or almost black. The appearance depends upon their age and also upon their structure, the younger colonies being more or less transparent, the older ones being generally opaque. They are generally of soft, sometimes tallow-like, consistence, though sometimes in the ox they are gritty, owing to the presence of calcareous deposit. They may be readily found in the pus by spreading it out in a thin layer on a glass slide and holding it up to the light. They are sometimes described as being always of a distinctly yellow colour, but this is only occasionally the case; in fact, in the human subject they occur much more frequently as small specks of semi-translucent appearance, and of greenish-grey tint.

Microscopical Characters.—In the colonies, as they grow in the tissues, three morphological elements may be described, namely, filaments, spores or gonidia, and clubs.

1. The *filaments* are comparatively thin, measuring about ·6 μ in diameter, but they are often of great length. They are composed of a central protoplasm enclosed by a sheath. The latter, which is most easily made out in the older filaments with granular protoplasm, occasionally contains granules of dark pigment. In the centre of the colony the filaments interlace with one another, and form an irregular network which may be loose or dense; at the periphery they are often arranged in a somewhat radiating manner, and run outwards in a wavy or even spiral course. They also show true branching, a character which at once distinguishes them from the ordinary bacteria. Between the filaments there is a finely granular or homogeneous ground substance. Most of the colonies at an early stage are chiefly constituted by filaments loosely arranged; but later, part of the growth may become so dense that its structure cannot be made out. This dense part, starting excentrically, may grow round the colony to form a hollow sphere, from the outer surface of which filaments radiate for a short distance (Fig. 90). The filaments usually stain uniformly in the younger colonies, but some, especially in the older colonies, may be segmented so as to give the appearance of a chain of bacilli or of cocci, though the sheath enclosing them may generally be distinguished. Rod-

shaped and spherical forms may also be seen lying free, some of the latter being gonidia.

2. *Spores or Gonidia.*—As occurs in other species of streptothrix, some of the filaments of the actinomyces when growing on a culture medium become segmented into rounded spores or gonidia. In natural conditions outside the body these gonidia become free, and act as new centres by growing out into fila-

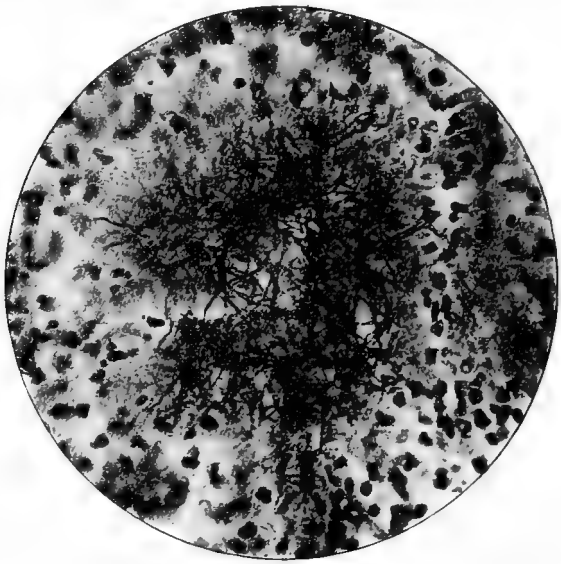

FIG. 90.—Actinomycosis of human liver, showing a colony of the parasite composed of a felted mass of filaments surrounded by pus. Paraffin section; stained by Gram's method and safranin. ×500.

ments. They have somewhat higher powers of resistance than the filaments, though less than the spores of most of the lower bacteria. An exposure to 75° C. for half an hour is sufficient to kill most streptothrices or their spores; cultures containing spores can resist a temperature from five to ten degrees higher than spore-free cultures (Foulerton). Both the filaments and the gonidia are readily stained by Gram's method. J. H. Wright found in the case of the streptothrix isolated by him from a number of cases (*vide infra*) that there was no distinct evidence of formation of gonidia.

3. *Clubs.*—These are elongated pear-shaped bodies which are seen at the periphery of the colony, and are formed by a sort of hyaline swelling of the sheath around the free extremity of a filament (Figs. 91, 92). They are usually homogeneous and structureless in appearance. In the human subject the clubs are often comparatively fragile structures, which are easily broken down, and may sometimes be dissolved in water. Sometimes

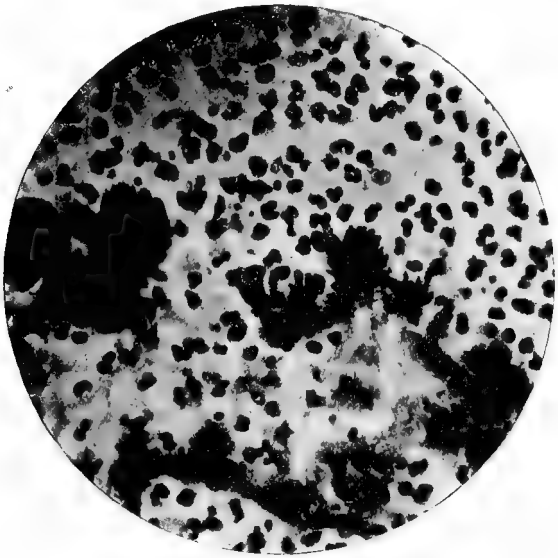

FIG. 91.—Actinomyces in human kidney, showing clubs radially arranged and surrounded by pus. The filaments had practically disappeared.
Paraffin section ; stained with hæmatoxylin and rubin. ×500.

they are well seen when examined in the fresh condition, but in hardened specimens are no longer distinguishable. In specimens stained by Gram's method they are usually not coloured by the violet, but take readily a contrast stain, such as picric acid, rubin, etc. ; sometimes a darkly-stained filament can be seen running for a distance in the centre, and may have a knob-like extremity. In many of the colonies in the human subject the clubs are absent. In the ox, on the other hand, where there are much older colonies, the clubs constitute the most prominent feature, and often form a dense fringe around the colony, staining

by Gram's method. Occasionally in very chronic lesions in the human subject the clubs stain with Gram's method. Clubs showing intermediate staining reaction have been described in the ox by McFadyean. The club formation probably represents a means of defence on the part of the parasite against the phagocytes of the tissue; the view, formerly held, that the clubs are organs of fructification has now been generally abandoned.

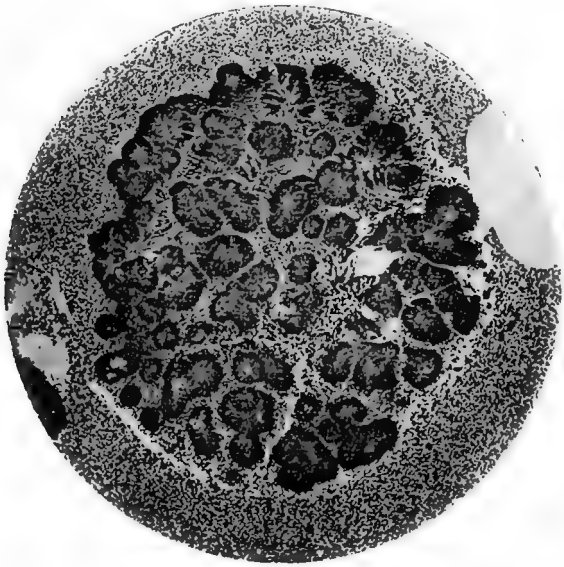

FIG. 92.—Colonies of actinomyces, showing general structural arrangement and clubs at periphery. From pus in human subject. Stained by Gram's method and safranin. ×60.

In the majority of cases in the ox no filaments can be detected in the colonies, and it is from such colonies that Lignières and Spitz have cultivated the *actinobacillus*.

Tissue Lesions.—In the human subject the lesions are of a chronic inflammatory type, usually ending in a spreading suppuration. In some cases there is a comparatively large production of granulation tissue, with only a little softening in the centre, so that the mass feels solid. In most cases, however, and especially in internal organs, suppuration is the outstanding feature; this is associated with abundant growth of the parasite

in the filamentous form. In an organ such as the liver, multiple foci of suppuration are seen at the spreading margin of the lesion, often presenting a honeycomb appearance, whilst the colonies of the parasite may be seen in the pus with the naked eye. In the older parts the abscesses have become confluent, and formed large areas of suppuration.

In cattle the tissue reaction is more of a formative type, there being abundant growth of granulation tissue, which may result in large tumour-like masses, usually of more or less nodulated character, and often consisting of well-developed fibrous tissue containing areas of younger formation, in which, however, irregular abscess formation may be present. The cells immediately around the colonies are usually irregularly rounded, or may even be somewhat columnar in shape, whilst farther out they become spindle-shaped and concentrically arranged. It is not uncommon to find leucocytes or granulation tissue invading the substance of the colonies, and portions of the parasite may be contained within leucocytes or within small giant-cells, which are sometimes present. A similar invasion of old colonies by leucocytes is sometimes seen in human actinomycosis. The disease usually remains quite local, or spreads by continuity. It may produce tumour-like masses in the region of the jaw or neck, or it may specially affect the palate or tongue, in the latter producing enlargement and induration, with nodular thickening on the surface—the condition known as "woody tongue."

Origin and Distribution of Lesions.—The lesions in the human subject may occur in almost any part of the body, the paths of entrance being very various. In many cases the entrance takes place in the region of the mouth—probably around a decayed tooth—by the crypts of the tonsil, or by some abrasion. Swelling and suppuration may then follow in the vicinity and may spread in various directions, the bones often becoming affected. In a considerable number of cases the primary lesion is in some part of the intestine, generally the large intestine, and not infrequently in connection with the appendix. A peculiar affection of the intestine has been described, in which slightly raised plaques are found both in the large and small intestines, these plaques being composed almost exclusively of masses of the actinomyces along with epithelial cells. This, however, is a rare condition. The path of entrance may also be by the respiratory passages, the primary lesion being pulmonary or peribronchial; extensive suppuration in the lungs may result. Infection may occur by the skin surface, and lastly, by the female genital tract, as in a case recorded by Grainger Stewart and Muir, in which both ovaries and both Fallopian tubes were affected.

When the parasite has invaded the tissues by any of these channels, secondary or "metastatic" abscesses may occur in

internal organs. The liver is the organ most frequently affected, though abscesses may occur in the lungs, brain (where a primary meningitis may also occur), kidneys, etc. In such cases the spread takes place by the blood stream, and it is possible that leucocytes may be the carriers of the infection, as it is not uncommon to find leucocytes in the neighbourhood of a colony containing small portions of the filaments in their interior.

FIG. 93.—Cultures of streptothrix actinomyces (Boström) on glycerin agar, of about three weeks' growth. The growth in A is at places somewhat corrugated on the surface. Natural size.

Source of the Parasite.—There is a certain amount of evidence to show that outside the body the parasite grows on grain, especially on barley. Both in the ox and in the pig the parasite has been found growing around fragments of grain, embedded in the tissues. There are besides, in the case of the human subject, a certain number of cases in which there was a history of penetration of a mucous surface by a portion of grain, and in a considerable proportion of cases the patient has been exposed to infection from this source. Doubt has, however, been recently thrown on this view (p. 328).

Cultivation (for methods of isolation see later).—The descriptions of the cultures obtained by various investigators differ in essential particulars, and there is no doubt that the organisms described are different. We give an account of the following as the most important:—

(1) *Streptothrix actinomyces* (*Boström*).—On *agar* or *glycerin agar* at 37° C., growth is generally visible on the third or fourth day in the form of little transparent drops which gradually

enlarge and form rounded projections of a reddish-yellow tint and somewhat transparent appearance, like drops of amber. The growths tend to remain separate, and even when they become confluent, the nodular character is maintained. They have a tough consistence, being with difficulty broken up, and adhere firmly to the surface of the agar. Older growths often show on the surface a sort of corrugated aspect, and may sometimes present the appearance of having been dusted with a brownish-yellow powder (Fig. 93).

In the cultures at an early stage the growth is composed of branching filaments, which stain uniformly (Fig. 94), but later some of the superficial filaments may show segmentation into gonidia. Slight bulbous thickenings may be seen at the end of some of the filaments, but true clubs have not been observed.

FIG. 94. — Actinomyces, from a culture on glycerin agar, showing the branching of the filaments. See also Plate III., Fig. 10. Stained with fuchsin. × 1000.

On *gelatin* the same tendency to grow in little spherical masses is seen, and the medium becomes very slowly liquefied. When this occurs the liquefied portion has a brownish colour and somewhat syrupy consistence, and the growths may be seen at the bottom, as little balls, from the surface of which filaments radiate.

Inoculation experiments have, on the whole, given negative results, and it has become doubtful whether this organism really plays a causal rôle in actinomycosis.

(2) *Streptothrix actinomyces* (*Israel and Wolff*).—The organism obtained in culture by Wolff and Israel (*vide infra*) is probably the same as the one which was later described in detail by J. H. Wright, who obtained it in pure condition from fifteen different cases of the disease. It differs markedly from Boström's organism in being almost a strict anaerobe and in ceasing to grow at a temperature a little below that of the body. Under ordinary aerobic conditions either no

growth occurs or it is of a very slight character. On the surface of agar under anaerobic conditions the organism produces dense rounded colonies of greyish-white colour, which sometimes assume a rosette form. A somewhat curious feature of growth is described by Wright, namely, that in a shake culture in glucose agar the colonies are most numerous and form a dense zone about half an inch from the surface of the medium, that is, at a level where there is presumably a mere trace of oxygen obtainable (Fig. 95). In bouillon, growth takes place at the bottom of the medium in rounded masses which afterwards undergo disintegration. Wright found that, when the organism was grown in the presence of serum or other animal fluids, the formation of true clubs occurred at the extremity of some of the filaments (Fig. 96). From the conditions under which growth occurs, he is inclined to regard it as a true parasite, and doubts whether it can have a saprophytic existence outside the body, *e.g.*, on grain. He is also of opinion that all cases of true actinomycosis, *i.e.*, cases where colonies visible to the naked eye are present, are probably produced by one species, and that the aerobic organisms obtained by Boström and others are probably accidental contaminations.

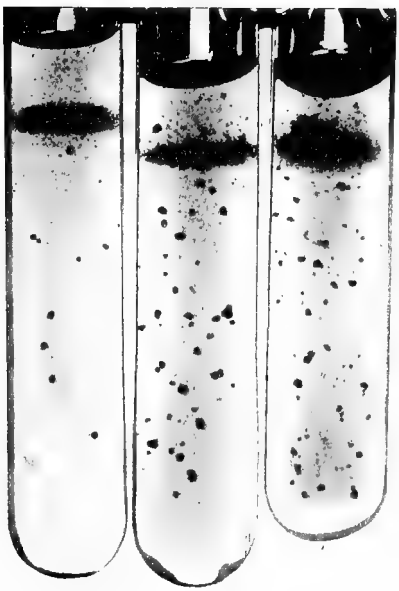

FIG. 95.[1]—Shake cultures of actinomyces in glucose agar, showing the maximum growth at some distance from the surface of the medium.

The views of Wright are supported by the recent observations of Harbitz and Gröndahl on actinomycosis in Norway. They obtained pure cultures from ten different cases, and in each

[1] For Figs. 95 and 96 we are indebted to Dr. J. Homer Wright of Boston, U.S.A.

instance the organism grew only under anaerobic conditions and presented the characters described above. They also obtained the same organism in culture from the disease in the ox. Henry also has cultivated from actinomycotic meningitis an organism which is a strict anaerobe and which corresponds in its characters.

Inoculation with the organism of Israel and Wolff in various animals, including guinea-pigs and rabbits, has given rise to granulomatous nodules, in which the characteristic granules are present, though the lesions usually have not a progressive character.

(3) *Actinobacillus* (*Lignières and Spitz*).—This organism was cultivated by these observers from a number of cases of actinomycosis in the ox, in which no filaments could be detected in the granules. It grows readily on most ordinary media. It is a small bacillus, measuring about 1·5 μ in length and 0·4 μ in thickness, Gram-negative and non-motile. On agar it forms in the primary cultures rounded semi-transparent colonies which reach 1·5 mm. in diameter; in sub-cultures it forms a continuous layer of similar character. Subcutaneous injection in the sheep and ox, and intraperitoneal injection in the guinea-pig, gave rise to lesions in which the characteristic granules with clubs are reproduced. These results have been substantially confirmed in this country by F. Griffiths, who obtained a similar organism in twenty-three out of forty cases of actinomycosis from the Argentine.

FIG. 96.—Section of a colony of actinomyces from a culture in blood serum, showing the formation of clubs at the periphery. ×1500.

Varieties of Actinomyces and Allied Forms.—Gasperini has described several varieties of *actinomyces bovis* according to the colour of the growths, and a similar condition may obtain in the case of the human subject. Furthermore, a considerable number of *streptothrices* have been found in cases of disease in the human subject, the associated lesions varying in character from tubercle-like nodules on the one hand to suppurative processes on the other. The organisms cultivated from such sources differ according to their microscopic characters (for example, some

form "clubs" whilst others do not), according to their conditions of growth, staining reactions, etc. Of these only a few examples may here be mentioned, but it may be noted that the importance of the streptothrices as causes of disease is constantly being extended. A species of streptothrix was cultivated by Eppinger from a brain abscess, and called by him "cladothrix asteroides," from the appearance of its colonies on culture media. A case of general streptothrix infection in the human subject described by Stuart M'Donald was probably due to the same organism as Eppinger's. In the tissues it grows in a somewhat diffuse manner, and does not form clubs; in rabbits and guinea-pigs it produces tubercle-like lesions. Flexner observed a streptothrix in the lungs associated with lesions somewhat like a rapid phthisis, and applied the name "pseudo-tuberculosis hominis streptothricea"; an apparently similar condition has been described by Buchholz. Berestnew cultivated two species of streptothrix from suppurative lesions, one of which is acid-fast and grows only in anaerobic conditions. Birt and Leishman have described another acid-fast streptothrix obtained from cirrhotic nodules in the lungs of a man. This organism grows readily on ordinary media, forming a white powdery growth which afterwards assumes a pinkish colour; it is pathogenic for guinea-pigs, in which it causes caseous lesions. There is, further, the streptothrix maduræ described below.

In diseases of the lower animals several other forms have been found. For example, a streptothrix has been shown by Nocard to be the cause of a disease of the ox,—"farcin du bœuf,"—a disease in which also there occur tumour-like masses of granulation tissue. Dean has cultivated from a nodule in a horse another streptothrix, which produces tubercle-like nodules in the rabbit with club-formation; it has close resemblances to the organism of Israel and Wolff. The so-called diphtheria of calves and "bacillary necrosis" in the ox are probably both produced by another streptothrix or leptothrix, which grows diffusely in the tissues in the form of fine felted filaments. Further investigation may show that some of these or other species may occur in the human subject in conditions which are not yet differentiated.

Methods of Examination and Diagnosis.—As actinomycosis cannot be diagnosed with certainty apart from the discovery of the parasite, a careful examination of the pus in obscure cases of suppuration should always be undertaken. As already stated, the colonies may be recognised with the naked eye, especially when some of the pus is spread out on a piece of glass. If some of these are washed in salt solution and examined unstained, the clubs, if present, are at once seen on microscopic examination. To study the filaments, a colony should be broken down on a cover-glass, dried, and stained with a simple solution of any of the basic aniline dyes, such as gentian-violet, though better results are obtained by carbol-thionin-blue, or by carbol-fuchsin diluted with five parts of water. If the specimen be overstained, it may be decolorised by weak acetic acid. Cover-glass preparations of this kind, and also of cultures, are readily stained by these methods, but in the case of sections of the tissues, Gram's method, or a modification of it, should be used to show the filaments, etc., a watery solution of acid fuchsin being afterwards used to stain the clubs. In the case of the disease in the ox the clubs are strikingly demonstrated by staining with carbol-fuchsin and then decolorising with picric alcohol; or the preparation may be decolorised with 1 per cent. sulphuric acid and then contrast-stained with methylene-blue.

Cultures should be made both under aerobic and anaerobic conditions. Tubes of agar or glycerin agar should be inoculated and incubated at 37° C.; deep tubes of melted glucose agar should also be used, the inoculated material being diffused through the medium, separate colonies may thus be obtained. Owing to the slow growth of the actinomyces, however, the obtaining of pure cultures is somewhat difficult, unless the pus is free from contamination with other organisms.

Madura Disease.

Madura disease or mycetoma resembles actinomycosis both as regards the general characters of the lesions and the occurrence of the parasite in the form of colonies or "granules." There is no doubt, however, that the two conditions are distinct, and it also appears established that the two varieties of Madura disease (*vide infra*) are produced by different organisms. This disease is comparatively common in India and in various other parts of the tropics: it has also been met with in Algiers and in America. Its course is of an extremely chronic nature, and though the local disease is incurable except by operation, the parasite never produces secondary lesions in internal organs. Vincent also found that iodide of potassium, which has a high value as a therapeutic agent in many cases of actinomycosis, had no effect in the case of Madura disease studied by him. It most frequently affects the foot; hence the disease is often spoken of as "Madura foot." The hand is rarely affected. In the parts affected there is a slow growth of granulation tissue which has an irregularly nodular character, and in the centre of the nodules there occurs purulent softening which is often followed by the formation of fistulous openings and ulcers. There are great enlargement and distortion of the part and frequently caries and necrosis of the bones. Within the softened cavities and also in the spaces between the fibrous tissue, small rounded bodies or

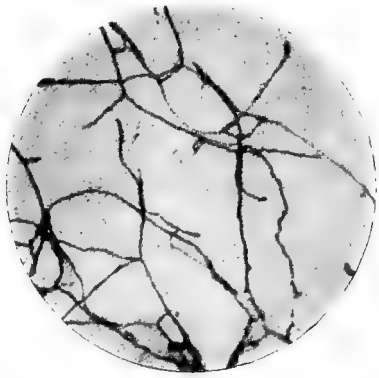

Fig. 97.—Streptothrix madurae, showing branching filaments. From a culture on agar.
Stained with carbol-thionin-blue. ×1000.

granules, bearing a certain resemblance to the actinomyces, are present. These may have a yellowish or pinkish colour, compared from their appearance to fish roe, or they may be black like grains of gunpowder, and may by their conglomeration form nodules of considerable size. Hence a *pale variety* and a *black variety* of the disease have been distinguished; in both varieties the granules mentioned reach a rather larger size than in "actinomycosis." These two varieties will be considered separately.

Pale Variety.—When the roe-like granules are examined microscopically they are found, like the actinomyces, to show in their interior an abundant mass of branching filaments with mycelial arrangement. There may also be present at the periphery club-like structures, as in actinomyces; sometimes they are absent. These structures often have an elongated wedge-shape, forming an outer zone to the colony, and in some cases the filaments can be found to be connected with them. Vincent obtained cultures of the parasite from a case in Algiers, and found it to be a distinct species: it is now known as the *streptothrix* or *discomyces maduræ*. Morphologically it closely resembles the actinomyces, but it presents certain differences in cultural characters. In gelatin it forms raised colonies of a yellowish colour, with umbilication of the centre, and there is no liquefaction of the medium. On agar the growth assumes a reddish colour; the organism also flourishes well in various vegetable infusions. On all the media growth only takes place in aerobic conditions. Experimental inoculation of various animals has failed to reproduce the disease.

Black Variety.—The observations of J. H. Wright, who obtained pure cultures of a hyphomycete, show that this variety is a distinct affection from the pale variety. The pigment may be dissolved by soaking the granules for a few minutes in hypochlorite of sodium solution, and the granules may then be crushed out beneath a cover-glass and examined microscopically. The granules are composed of a somewhat homogeneous ground-substance impregnated with pigment, and in this there is a mycelium of thick filaments or hyphæ, many of the segments of which are swollen; at the periphery the hyphæ form a zone with radiate arrangement. In many of the older granules the parasite is largely degenerated and presents an amorphous appearance. Wright planted over sixty of the black granules in various culture media, and obtained cultures of a hyphomycete from about a third of these. The organism grows well on agar, bouillon, potato, etc.; on agar it forms a felted mass of greyish colour, and in old cultures black granules appear amongst the

mycelium. Microscopically the parasite appears as a mycelium of thick branching filaments with delicate transverse septa; in the older threads the segments become swollen, so that strings of oval-shaped bodies result. No signs of spore-formation were noted. Inoculation of animals with cultures gave negative results, as did also direct inoculation with the black granules from the tissues. Brumpt, in a recent work, distinguishes several varieties of parasite concerned in Madura disease, and finds that a pale variety may be produced by a hyphomycete as well as by Vincent's streptothrix; in fact, with the exception of Vincent's organism, all the parasites are considered by him to be closely allied to aspergillus.

CHAPTER XIV.

ANTHRAX.

OTHER NAMES.—SPLENIC FEVER, MALIGNANT PUSTULE, WOOL-SORTER'S DISEASE; *GERMAN*, MILZBRAND; *FRENCH*, CHARBON.[1]

Introductory.—Anthrax is a disease occurring epidemically among the herbivora, especially sheep and oxen, in which animals it has the characters of a rapidly fatal form of septicæmia with splenic enlargement, attended by an extensive multiplication of characteristic bacilli throughout the blood. The disease does not occur as a natural infection from man to man, but may be communicated to him directly or indirectly from animals, and it may then appear in one of three forms. In all of these forms in the human subject, the bacilli are in their distribution much more restricted to the local lesions than is the case in the ox, their growth and spread being attended by inflammatory œdema and often by hæmorrhages.

Historical Summary.—Historical researches leave little doubt that from the earliest times anthrax has occurred among cattle. For a long time its pathology was not understood, and it went by many names. Pollender in 1849 pointed out that the blood of anthrax animals contained numerous rod-shaped bodies which he conjectured had some causal connection with the disease. In 1863 Davaine announced that they were bacteria, and originated the name *bacillus anthracis*. He stated that unless blood used in inoculation experiments on animals contained them death did not ensue. Though this conclusion was disputed, still by the work of Davaine and others the causal relationship of the bacilli to the disease had been nearly established when the work of Koch appeared in 1876. This not only did much to clear up the whole subject, but formed the starting-point of the science of bacteriology. Koch confirmed Davaine's view that the bodies were bacteria. He observed in the blood of anthrax animals the appearance of division, and from this deduced that multiplication took place in the tissues. He observed them under the microscope dividing outside the body, and noticed spore-formation taking place. He also isolated the bacilli in pure culture

[1] This must be distinguished from "charbon symptomatique," which is quite a different disease.

outside the body, and, by inoculating animals with them, produced the disease artificially. Koch's observations were, shortly afterwards, confirmed in the main by Pasteur, though controversy arose between them on certain minor points. Moreover, further research showed that the disease could be produced in animals by feeding them with spores, and thus the way in which the disease might spread naturally was explained.

Bacillus Anthracis.—Anthrax as a disease in man is of comparative rarity. Not only, however, is the bacillus anthracis easy of growth and recognition, but in its growth it illustrates many of the general morphological characters of the whole group of bacilli, and it is therefore of great use to the student. Further, its behaviour when inoculated in animals illustrates many of the points raised in connection with the general pathogenic effects of bacteria. Hence an enormous amount of work has been done in investigating it in all its aspects.

If a drop of blood is taken immediately after death from an auricular vein of an ox, for example, which has died from anthrax, it will be found to contain a great number of large non-motile bacilli. On staining with watery methylene-blue, the characters of the bacilli can be better made out. They are about 1·2 μ thick or a little thicker, and 6 to 8 μ long, though both shorter and longer forms also occur. The ends are sharply cut across, or may be slightly dimpled so as to resemble somewhat the proximal end of a phalanx. Their protoplasm is very finely granular, and very frequently appears surrounded by a capsule whose external margin is often not, however, so well defined as is the case with, *e.g.*, the pneumococcus. When several bacilli lie end to end in a thread, the capsule seems common to the whole thread. They stain well with all the basic aniline dyes and are Gram-positive. To demonstrate the capsule the preparation is well stained with aniline-oil gentian-violet solution, rapidly differentiated in water acidulated with acetic acid, and mounted in water.

Methylene-blue Reaction.—This was introduced independently by McFadyean and by Heim with a view to the easy recognition of the bacilli in blood or other bodily fluids, and depends on a disintegration of the bacillary capsules which occurs when these are imperfectly fixed. Imperfect fixation is attained by drying a blood film on a *slide* and holding it three times for a second in a flame, film upwards (too great heating fixes the capsules and prevents the reaction from occurring). The preparation is stained for a few seconds with an old solution of methylene-blue, 1 per cent. in water (*i.e.*, with a methylene-blue possessing polychromatic qualities, see p. 111). It is washed in water and dried with filter paper,—preferably a cover-glass is not applied. In such a prepara-

tion, between and near the bacteria there is a varying amount of an irregularly disposed amorphous or finely granular material of a violet or reddish-purple tint. Frequently the colour reaction in the preparation is so marked as to be recognisable to the naked eye. McFadyean states that this reaction does not occur with putrefactive or other bacteria which might be present under circumstances where the recognition of the anthrax bacilli is the question under consideration.

Plate Cultures.—From a source such as that indicated, it is easy to isolate the bacilli by making agar plates. If, after twelve hours at 37° C., these be examined under a low objective, colonies will be observed. They are to be recognised by beautiful wavy wreaths like locks of hair, radiating from the centre and apparently terminating in a point which, however, on examination with a higher power, is observed to be a filament which turns upon itself (Fig. 98). Graham-Smith (*vide* p. 4) attributes the appearance to the toughness of the bacterial envelope, which prevents the separation of individuals from one another after division. The colonies are suitable for making impression preparations (*vide* p. 134) which preserve permanently the appearances described. On examining such with a high power, the wreaths are seen to be made up of bundles of long filaments lying parallel with one another, each filament consisting of a chain of bacilli lying end to end, and similar to those observed in the blood (Fig. 99).

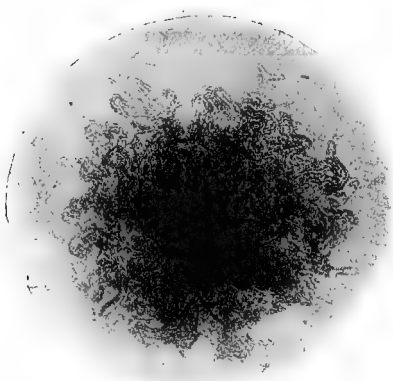

FIG. 98.—Surface colony of the anthrax bacillus on an agar plate, showing the characteristic appearance. ×30.

On gelatin plates, after from twenty-four to thirty-six hours at 20° C., the same appearances manifest themselves, and later they are accompanied by liquefaction of the gelatin. In gelatin plates, however, instead of the characteristically wreathed appearance at the margin, the colonies sometimes give off radiating spikelets irregularly jointed, nodulated, and whorled, which produce a star-like form. These spikelets are composed of spirally twisted threads.

From plates the bacilli can be easily isolated, and the appearances of pure cultures on various media studied.

In *bouillon*, after twenty-four hours' incubation at 37° C.,

FIG. 99.—Anthrax bacilli arranged in chains, from a twenty-four hours' culture on agar at 37° C.
Stained with fuchsin. ×1000.

there is usually the appearance of irregular spiral threads suspended in the liquid. These, on being examined, are seen to be made up of bundles of parallel chains of bacilli. Later, growth is more abundant, and forms a flocculent mass at the bottom of the fluid.

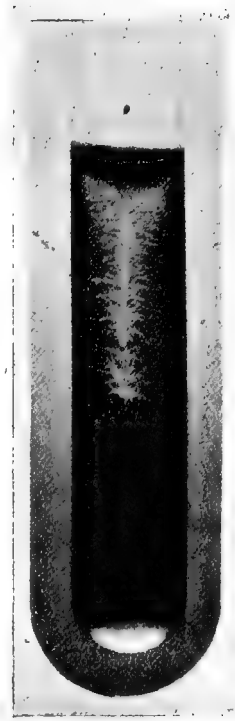

FIG. 100.—Stab culture of the anthrax bacillus in peptone-gelatin; seven days' growth. It shows the "spiking," and also, at the surface, commencing liquefaction. Natural size.

In *gelatin* stab cultures, the characteristic appearance can be best observed when a low proportion, say, 7½ per cent., of gelatin is present, and when the tube is directly inoculated from anthrax blood. In about two days there radiate out into the medium from the needle track numberless very fine spikelets which enable the cultures to be easily recognised. These spikelets are longest at the upper part of the needle track (Fig. 100). Not much spread takes place on the surface of the gelatin, but here liquefaction commences, and gradually spreads down the stab and out into the medium, till the whole of the

gelatin may be liquefied. Gelatin slope cultures exhibit a thick felted growth, the edges of which show the wreathed appearance seen in plate cultures. Liquefaction here soon ploughs a trough in the surface of the medium. Sometimes "spiking" does not take place in gelatin stab cultures, only little round particles of growth occurring down the needle track, followed by liquefaction. As has been shown by Rd. Muir, this property of spiking can be restored by growing the bacillus for twenty-four hours on blood-agar at 37° C. *Agar* sloped cultures have the appearance of similar cultures in gelatin, though, of course, no liquefaction takes place. On these sporulation can be readily developed. The organism grows readily on *blood serum* and *potato*, but the cultures show no special characteristics.

The Biology of the B. Anthracis.—Koch found that the bacillus anthracis grows best at a temperature of 35° C. Multiplication does not take place below 12° C. nor above 45° C. In the spore-free condition the bacilli have comparatively low powers of resistance. They do not stand long exposure to 60° C., and if kept at ordinary temperature in the dry condition they are usually found to be dead after a few days. The action of the gastric juice is rapidly fatal to them, and they are accordingly destroyed in the stomachs of healthy animals. They are also soon killed in the process of putrefaction. They can, however, be cooled below the freezing-point without dying. The bacillus can grow without oxygen, but some of its vital functions are best carried on in the presence of this gas. Thus in anthrax cultures the liquefaction of gelatin always commences at the surface and spreads downwards. Growth is more rapid in the presence of oxygen, and spore-formation does not occur in its absence. The organism may be classed as a facultative anaerobe.

Sporulation.—Under certain circumstances sporulation occurs in anthrax bacilli. The morphological appearances are of the ordinary kind. A little highly refractile speck appears in the protoplasm about the centre of the bacillus; this gradually increases in size until it forms an oval body of about the same thickness as the bacillus lying in the bacillary protoplasm (Fig. 101). The latter gradually loses its staining capacities and finally disappears. The spore thus lies free as an oval highly refractile body which does not stain by ordinary methods, but which can be easily stained by the special methods described for such a purpose (p. 106). When the spore is again about to assume the bacillary form the capsule is apparently absorbed, and the protoplasm within grows out, taking on the ordinary rod-shaped form.

It is generally agreed that sporulation never occurs within the body of an animal suffering from anthrax. Koch attributed this to the absence of free oxygen. The latter gas he found necessary to the occurrence of spores in cultures outside the body. Many, however, are inclined to assign as the cause of sporulation the absence of the optimum pabulum. Besides these conditions there is another factor necessary to sporulation, namely, a suitable temperature. The optimum temperature for spore production is 30° C. Koch found that spore-formation did not occur below 18° C. Above 42° C. not only does sporulation cease, but Pasteur found that if bacilli were kept at this temperature for eight days they did not regain the capacity when again grown at a lower temperature. In order to make them again capable of sporing, it is necessary to adopt special measures, such as passages through the bodies of a series of susceptible animals.

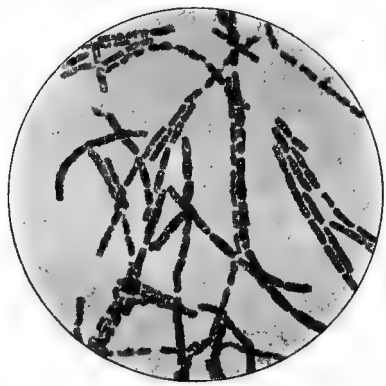

FIG. 101.—Anthrax bacilli containing spores (the darkly coloured bodies); from a three days' culture on agar at 37° C. See also Plate III. Fig. 2. Stained with carbol-fuchsin and methylene-blue. ×1000.

Anthrax spores have extremely high powers of resistance. In a dry condition they will remain viable for a year or more. Koch found they resisted boiling for five minutes; and dry heat at 140° C. must be applied for several hours to kill them with certainty. Unlike the bacilli, they can resist the action of the gastric juice for a long period of time. They are often used as test objects by which the action of germicides is judged (see Chap. VI.).

Capsulation.—This is very frequently observed in the b. anthracis both in tissues and in cultures, but the appearances vary under different biological conditions and sometimes capsule formation is absent. The capsule sometimes has as sharp an external contour as occurs in the pneumococcus, but in other cases is not so definitely marked, and sometimes when bacilli are lying together their capsules appear to blend to form a somewhat ill-defined halo. Such variations are associated with

slight differences in the naked-eye appearance and physical characters of surface growths. In those where the capsule is indefinite, the growth is moister and more slimy and the edges of the colonies may not present the typical wreathed appearances already described. Such variations have been noted by Preisz as of special frequency in strains deprived of their power of sporulation by heat, and different colonies isolated from such strains may present differences in the character of the capsule. There is a general opinion that capacity to produce a well-formed firm capsule is associated with the possession of special virulence, non-capsulating strains frequently showing low pathogenic qualities. According to Ottolenghi, in cultures the capsule is formed from the carbo-hydrates present.

It is evident from what has been said that modifications in both biological and cultural characters can be artificially originated in anthrax bacilli. These observations are important in relation to the fact that from material where the anthrax bacillus might be present, organisms closely resembling it have been isolated, the differences relating to details in the appearance of cultures and to variations in pathogenic properties. The problem thus arises whether these are to be looked on as modifications of the true anthrax bacillus or whether, as with other organisms, there exists in nature a group of closely allied bacteria.

Anthrax in Animals.—Anthrax occurs from time to time epidemically in sheep, cattle, and, more rarely, in horses and deer. These epidemics are found in various parts of the world, although they are naturally most far-reaching where legal precautions to prevent the spread of infection are non-existent. All the countries of Europe are from time to time visited by the disease, but in some it is much more common than in others. In Britain the death-rate is small, and often only one animal in a herd is affected, but in France the annual mortality among sheep was formerly about 10 per cent. of the total number in the country, and among cattle 5 per cent. These figures, however, have been largely modified by the system of preventive treatment which will be presently described. In sheep and cattle the disease is specially virulent. An animal may suddenly drop down, with symptoms of collapse, quickening of pulse and respiration, and dyspnœa, and death may occur in a few minutes. In less acute cases the animal is apparently out of sorts, and does not feed; its pulse and respiration are quickened; rigors occur, succeeded by high temperature; there is a sanguineous discharge from the bowels, and bloody mucus may be observed about the mouth and nose. There may be con-

vulsive movements; and progressive weakness, with cyanosis, is followed by death in from twelve to forty-eight hours. In the more prolonged cases widespread œdema and extensive enlargement of lymphatic glands are marked features; and in the glands, especially about the neck, actual necrosis with ulceration may occur, constituting the so-called anthrax carbuncles. Such subacute conditions are especially found among horses, which are by nature not so susceptible to the disease as cattle and sheep. Occasionally even in susceptible animals recovery takes place.

On post-mortem examination of an ox dead of anthrax, the most noticeable feature—one which has given the name "splenic fever" to the disease—is the enlargement of the spleen, which may be two or three times its natural size. It is of dark-red colour, and on section the pulp is very soft and friable, sometimes almost diffluent. A film made from the spleen and stained with watery methylene-blue will be found to contain enormous numbers of bacilli mixed with red corpuscles and leucocytes, chiefly lymphocytes and the large mononucleated variety (Fig. 102). Paraffin sections stained by Gram's method show that the structure of the pulp is considerably disintegrated, whilst the bacilli swarm throughout the organ, lying irregularly amongst the cellular elements. The liver is enlarged and congested, and may be in a state of acute cloudy swelling. The bacilli are present in the capillaries throughout the organ, but are not so numerous as in the spleen. The kidney is in a similar condition, and here the bacilli are chiefly found in the capillaries of the glomeruli, which often appear as if injected with them. The lungs are congested and may show catarrh, whilst bacilli are present in large numbers throughout the capillaries, and may also be found in the air cells, probably as the result of rupture of the capillaries. The blood throughout the body is usually fluid and of dark colour.

The lymphatic system generally is much affected. The glands, especially the mediastinal, mesenteric, and cervical glands, are enlarged and surrounded by œdematous tissue, the lymphatic vessels are swollen, and both glands and vessels may contain numberless bacilli. The heart-muscle may be in a state of cloudy swelling, and the blood in its cavities contains bacilli, though in smaller numbers than that in the capillaries. The intestines are enormously congested, the epithelium more or less desquamated, and the lumen filled with a bloody fluid. From all the organs the bacilli can be easily isolated by stroke cultures on agar.

Great differences exist in susceptibility to anthrax in different species of animals. Thus the ox, sheep (except those of Algeria, which only succumb to enormous doses of the bacilli), guinea-pig, and mouse are all very susceptible, the rabbit slightly less so. We have no data to determine whether the disease occurs among the last three in the wild state. Less susceptible than this group are the horse, deer, and goat, in which the disease occurs

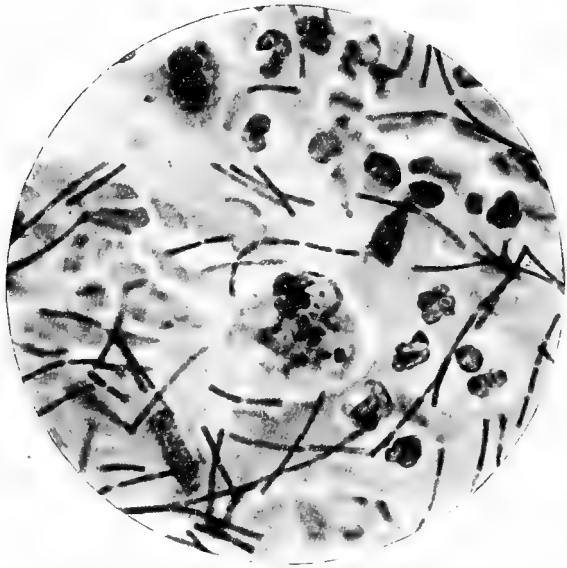

FIG. 102.—Scraping from spleen of guinea-pig dead of anthrax, showing the bacilli mixed with leucocytes, etc. (Same appearance as in the ox.)
"Corrosive film" stained with carbol-thionin-blue. ×1000.

from time to time in nature. Anthrax also occurs epidemically in the pig, often from the ingestion of the organs of other animals dead of the disease. It is, however, doubtful if all cases of disease in the pig described on clinical grounds as anthrax are really such. A careful bacteriological examination is here always advisable, especially of any œdematous infiltration about the throat, or in the neighbouring lymphatic glands; often, in pigs dying of anthrax, bacilli may not occur in the blood. Any hæmorrhagic infarction in the spleen of a suspected animal should be carefully investigated. The human subject

may be said to occupy a medium position between the highly susceptible and the relatively immune animals. The white rat is highly immune to the disease, while the brown rat is susceptible. Adult carnivora are also very immune, and birds and amphibia are in the same position.

With these differences in susceptibility there are also great variations in the pathological effects produced in the natural or

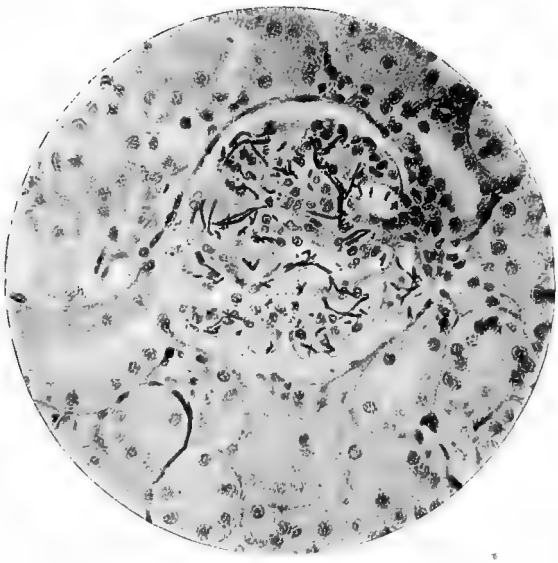

FIG. 103.—Portion of kidney of a guinea-pig dead of anthrax, showing the bacilli in the capillaries, especially of the glomerulus. Paraffin section; stained by Gram's method and Bismarck-brown. ×300.

artificial disease. This is especially the case when we consider the distribution of the bacilli in the bodies of the less susceptible animals. Instead of the widespread occurrence described above, they may be confined to the point where they first gained access to the body and the lymphatic system in relation to it, or may be only very sparsely scattered in organs such as the spleen (which is often not enlarged), the lungs, or kidneys. Nevertheless the cellular structure of the organs even in such a case may show changes, a fact which is important, when we consider the essential pathology of the disease.

Experimental Inoculation.—Of the animals commonly used in laboratory work, mice and guinea-pigs are the most susceptible to anthrax, and are generally used for test inoculations. If a small quantity of anthrax bacilli be injected into the subcutaneous tissue of a guinea-pig, a fatal result follows, usually within two days. *Post mortem*, around the site of inoculation the tissues, owing to intense inflammatory œdema, are swollen and gelatinous in appearance, small hæmorrhages are often present, and on microscopic examination numerous bacilli are seen. The internal organs show congestion and cloudy swelling, with sometimes small hæmorrhages, and their capillaries contain enormous numbers of bacilli, as has already been described in the case of the ox (Fig. 103); the spleen also shows a corresponding condition. Highly susceptible animals may be infected by being made to inhale the bacilli or their spores, and also by being fed with spores, a general infection rapidly occurring by both methods.

Anthrax in the Human Subject.—As we have noted, man occupies a middle position in the scale of susceptibility to anthrax. It is always communicated to him from animals directly or indirectly, and usually is seen among those whose trade leads them to handle the carcases or skins of animals which have died of the disease. It occurs in two principal forms, the main difference between which is due to the site of entrance of the organism into the body. In one, the path of entrance is through cuts or abrasions in the skin, or through the hair follicles. A local condition called a "malignant pustule" develops, which may lead to a general infection. This variety occurs chiefly among butchers and those who work among hides (foreign ones especially). In Britain the workers of the latter class chiefly liable are the hide-porters and hide-workers in South-Eastern London. Occasionally the disease has been contracted from anthrax spores in shaving-brushes. In the other variety of the disease the site of infection is the trachea and bronchi, and here a fatal result almost always follows. The cause is the inhalation of dust or threads from wool, hair, or bristles, which have been taken from animals dead of the disease, and which have been contaminated with blood or secretions containing the bacilli, these having afterwards formed spores. This variety is often referred to as "woolsorter's disease," from its occurring in the centres of the woolstapling trade (in England, chiefly in Yorkshire), but it also is found in places where there are hair, brush, or carpet factories.

(1) *Malignant Pustule.*—This usually occurs on the exposed surfaces—the face, hands, forearms, and back, the last being a

common site among hide-porters. One to three days after inoculation a small red painful pimple appears, soon becoming a vesicle, which may contain clear or blood-stained fluid; it is rapidly surrounded by an area of intense congestion. Central necrosis occurs and leads to the malignant pustule proper, which in its typical form appears as a black eschar of irregular shape often surrounded by a ring of vesicles, these in turn being surrounded by a congested area. From this pustule as a centre subcutaneous œdema spreads, especially in the direction of the lymphatics; the neighbouring glands are enlarged. There is usually fever with general malaise. On microscopic section of the typical pustule, the central eschar is noticed to be composed of necrosed tissue and degenerating blood cells; the vesicles are formed by the raising of the stratum corneum from the rete Malpighii. Beneath them and in their neighbourhood the cells of the latter are swollen and œdematous, the papillæ being enlarged and flattened out and infiltrated with inflammatory exudation, which also extends beneath the centre of the pustule. In the tissue next the eschar necrosis is commencing. The subcutaneous tissue is also œdematous, and often infiltrated with leucocytes. The bacilli exist in the periphery of the eschar and in the neighbouring lymphatics, and, to a certain extent, in the vesicles. It is very important to note that widespread œdema of a limb, enlargement of neighbouring glands, and fever may occur while the bacilli are still confined to the immediate neighbourhood of the pustule. Sometimes the pathological process goes no further, the bacilli gradually die out, the eschar becomes a scab, the inflammation subsides, and recovery takes place. In the majority of cases, however, if the pustule be not excised, the œdema spreads, invasion of the blood stream may occur, and the patient dies with, in a modified degree, the pathological changes detailed with regard to the acute disease in cattle. In man the spleen is usually not much enlarged, and the organs generally contain few bacilli. The actual cause of death is therefore a toxic effect. The early excision of an anthrax pustule, especially when it is situated in the extremities, is followed, in a large proportion of cases, by recovery.

(2) *Woolsorter's Disease.*—The pathology of this affection was worked out in this country especially by Greenfield. The local lesion is usually situated in the lower part of the trachea or in the large bronchi, and is in the form of swollen patches in the mucous membrane, often with hæmorrhage into them,—small ulcers may also be seen. The tissues are intensely inflamed, œdematous, and the cellular elements are separated, but there

is usually little or no necrosis. There is enormous enlargement and engorgement of the mediastinal and bronchial glands, and hæmorrhagic infiltration of the cellular tissue in the region. There are pleural and pericardial effusions, and hæmorrhagic spots occur beneath the serous membranes. The lungs show great congestion, collapse and œdema. There may be cutaneous œdema over the chest and neck, with enlargement of glands, and the patient rapidly dies with symptoms of pulmonary embarrassment, and with a varying degree of pyrexia. It is to be noted that in such cases, though numerous bacilli are present in the bronchial lesions, in the lymphatic glands, and affected tissues in the thorax, comparatively few may be present in the various organs, such as the kidney, spleen, etc., and sometimes it may be impossible to find any.

(3) Infection occasionally takes place through the intestine, probably by ingestion of spores as in the case of animals; but this condition is rare. In such cases there occur single or multiple local hæmorrhagic lesions in the intestinal mucous membrane, the central parts of the hæmorrhagic areas tending to be necrotic and yellowish, and there may be a corresponding affection of the mesenteric glands.

A considerable number of cases have been recorded in which hæmorrhagic meningitis, associated with the presence of the anthrax bacilli in large numbers, has occurred as a complication of various primary lesions.

The Spread of the Disease in Nature.—We have seen that the b. anthracis rarely, if ever, forms spores in the body, and if the bacilli could be confined to the blood and tissues of carcases of animals dying of the disease, it is certain that anthrax in an epidemic form would be less frequent. For it has been shown by many observers that in the course of the putrefaction of such a carcase the anthrax bacilli rapidly die out, and that after ten days or a fortnight very few remain. But it must be remembered that while still alive an animal is shedding into the air by the bloody excretions from the mouth, nose, and bowel, myriads of bacilli which may rapidly spore, and thus arrive at a very resistant stage. These lie on the surface of the ground and are washed off by surface water. At certain seasons of the year the temperature is, however, sufficiently high to permit of their germination and multiplication, as they can undoubtedly grow on the organic matter which occurs in nature. They can again form spores. It is in the condition of spores that they are dangerous to susceptible animals. In the bacillary stage, if swallowed, they will be killed by the acid gastric contents; but

as spores they can pass uninjured through the stomach, and gaining an entrance into the intestine, infect its wall, and ultimately reach, and multiply in, the blood. It is known that in the great majority of cases of the disease in sheep and oxen, infection takes place thus from the intestine. It was thought by Pasteur that worms were active agents in the natural spread of the disease by bringing to the surface anthrax spores. Koch made direct experiments on this point, and could get no evidence that such was the case. He thought it much more probable that the recrudescence of epidemics in fields where anthrax carcases have been buried is due to persistence of spores on the surface which has been infected by the cattle when alive. In Britain it is common to attribute the occurrence of sporadic outbreaks to infection by imported feeding stuffs. Scientific proof of such a method of infection being common is at present wanting.

The Disposal of the Carcases of Animals dead of Anthrax.—It is extremely important that anthrax carcases should be disposed of in such a way as to prevent their becoming future sources of infection. If anthrax be suspected as the cause of death, no post-mortem examination should be made, but only a small quantity of blood removed from an auricular vein for bacteriological investigation. If such a carcase be now buried in a deep pit surrounded by quicklime, little danger of infection will be run. The bacilli being confined within the body will not spore, and will die during the process of putrefaction. The danger of sporulation taking place is, of course, much greater when an animal has died of an unknown disease, which, on post-mortem examination, has proved to be anthrax, but similar measures for burial must be here adopted. In some countries anthrax carcases are burned, and this, if practicable, is of course the best means of treating them. The chief source of danger to cattle subsequently, however, proceeds from the infection of fields, yards, and byres with the offal and the discharge from the mouths of anthrax animals. All material suspected of being infected should be burned along with the straw in which the animals have lain. The stalls or buildings in which the anthrax cases have been must be limewashed. Needless to say, the greatest care must be taken in the case of men who handle the animal or its carcase that they have no wounds on their persons, and that they thoroughly disinfect themselves by washing their hands, etc., in 1 to 1000 solution of corrosive sublimate or lysol, and that all clothes soiled with blood, etc., from anthrax animals be thoroughly boiled or steamed for half an hour before being washed.

The Immunising of Animals against Anthrax.—Having ascertained that there was ground for believing that in cattle one attack of anthrax protected against a second, Pasteur (in the years 1880–82) elaborated a method by which a mild form of the disease could be given to animals, which rendered harmless a subsequent inoculation with virulent bacilli. He

found that the continued growth of anthrax bacilli at 42° to 43° C. caused them to lose their capacity of producing spores, and also gradually to lose their virulence, so that after twenty-four days they could no longer kill either guinea-pigs, rabbits, or sheep. Such cultures constituted his *premier vaccin*, and protected against the subsequent inoculation with bacilli which had been grown for twelve days at the same temperature, and the attenuation of which had therefore not been carried so far. The latter constituted the *deuxième vaccin*. It was further found that sheep thus twice vaccinated now resisted inoculation with a culture which usually would be fatal. The method was to inoculate a sheep on the inner side of the thigh by the subcutaneous injection, from a hypodermic syringe, of about five drops of the *premier vaccin*; twelve days later to again inoculate with the *deuxième vaccin*; fourteen days later an ordinary virulent culture was injected without any ill result. This method was applicable also to cattle and horses, about double the dose of each vaccine being here necessary. Extended experiments in France generally confirmed earlier results, and the method was, before long, used to mitigate the disease, which in many *départements* was endemic and a very great scourge. Since that time the method has been regularly in use. It is difficult to arrive at a certain conclusion as to its merits. Undoubtedly a certain number of animals die of anthrax either after the first or second vaccination, or during the year following vaccination. At the end of a year the immunity is lost in about 40 per cent. of the animals vaccinated; and thus to be permanently efficacious the process would have to be repeated every year. Further, the immunity is much higher in degree if, after the first and second vaccinations, an inoculation with virulent anthrax is performed. Everything being taken into account, however, there is no doubt that the mortality from natural anthrax is much diminished by this system.

In France, during the twelve years 1882–93, 3,296,815 sheep were vaccinated, with a mortality, either after the first or second vaccination, or during the subsequent twelve months, of 0·94 per cent., as contrasted with the ordinary mortality in all the flocks of the districts of 10 per cent. During the same time 438,824 cattle were vaccinated, with a mortality of 0·34 per cent., as contrasted with a probable mortality of 5 per cent. if they had been unprotected.

The immunisation of animals against anthrax has always been found to be a difficult proceeding. The most usual technique has been to commence with Pasteur's vaccines, and to follow these by careful dosage with virulent cultures. Marchoux

in this way produced immunity, and found that the serum of immune animals had a certain degree of protective and curative action. The most successful attempts in this direction have been those of Sclavo and of Sobernheim. The former observer, after trying various animals, came to the conclusion that the ass was the most suitable for the obtaining of the anti-serum. He first employed a method similar to that of Marchoux; later, however, after noting the effects of the serum of an animal so immunised, he commenced the immunisation by injecting 5 to 15 c.c. of this serum along with a slightly attenuated culture of the bacilli. A few days later this was followed up with injections of virulent cultures which could now be periodically introduced for many months, and a high degree of immunity resulted. What was even more important, the serum of such an animal had strongly protective and curative properties. It has been extensively used in the treatment of anthrax in man. In a case of malignant pustule 30 to 40 c.c. are injected in quantities of 10 c.c. into the abdominal wall, and if necessary the injection is repeated on the following day. In cases treated by Sclavo himself the serum is alone employed, and its action is not aided by the excision of the pustule usually practised. The results obtained have been very good—Sclavo, out of 164 cases, had only ten deaths, or about a fourth of the ordinary mortality in Italy. Sobernheim independently elaborated an almost identical method of combining passive with active immunisation for the obtaining of a powerful anti-serum, and he has used the same principle for the protective inoculation of cattle. The technique is to inject a mixed serum obtained from the ox, the horse, and the sheep, into one side of the neck or into one thigh and the culture (Pasteur's second vaccine) into the other side; the doses given are for cattle or horses 5 c.c. of serum and 0·5 c.c. culture, and for sheep 4 c.c. of serum and 0·25 c.c. culture. The method has been widely used in Germany and in Brazil, and its originator claims as its advantages simplification of application, in that one operation instead of two is sufficient, less risk of death following the immunisation procedure, and higher degree and more lasting character of the immunity resulting. During the development of active immunity it is likely in every case (see Immunity) that there is a period of increased susceptibility to the disease. Such a period would be more likely to occur with the Pasteur method than with the Sobernheim procedure, where the presence in the animal's body of the protective serum might tide it over the stage when the action of the vaccine was lowering its resistance.

The Pathology of Anthrax.—Various theories were formerly held as to the mode in which the anthrax bacillus produces its effects. One of the earliest was the mechanical, according to which it was supposed that the serious results were produced by extensive blocking of the capillaries in the various organs by the bacilli. According to another, it was supposed that the bacilli used up the oxygen of the blood, thus leading to starvation of the tissues. In modern times there has been a tendency to attribute the effects produced to toxic action. That toxic effects do occur in anthrax is probable, for frequently while the bacilli are still locally confined, there may occur pyrexia and œdema spreading widely beyond the pustules. All attempts, however, to throw further light on the toxic process have hitherto been unsuccessful. In the opinion of some, the anthrax bacillus shows a special tendency to be broken up in the infected tissues, and substances derived from its protoplasm may thus be readily distributed throughout the body. According to Bail there is in anthrax an aggressin intoxication, and in support of this he states that the protective action of an anthrax immune-serum is due to its containing anti-aggressins. It may be stated that the alleged aggressins have been obtained by centrifuging the œdematous fluid from the point of inoculation or the pleural exudates occurring in infected animals, and killing any remaining bacilli by shaking the fluid with toluol.

The effects of the b. anthracis have been much studied with a view to the shedding of light on the processes obtaining in resistance and the development of immunity. Many puzzling facts have long been known; for example, in the dog, which shows great natural resistance, the serum has little if any bactericidal action, while the serum of the susceptible rabbit is capable of killing the organism. Again, the properties of the serum of immunised animals have been much discussed. Sobernheim and others have been unable to detect in it any trace of special bactericidal action. Sclavo found that the serum when heated to 55° C. did not lose its protective properties, and holds the view that, in the action of the serum, substances of the nature of immune-body and complement are not concerned. Many have thought that the serum had a stimulating effect on the leucocytes, but Cler has brought forward ground for supposing that its effect is a sensitising one on the bacteria, and that thus the effects are to be traced to opsonic action. With regard to the formation of the protective substances, it is stated that the spleen and bone-marrow are richer in these than the blood fluids. In this connection an

interesting fact may be mentioned, namely, that Roger and Garnier found evidence of the liver and spleen having special capacities for killing anthrax bacilli; an otherwise fatal dose could be introduced into the portal vein or the splenic artery without causing death. It has been thought that the capsule of the anthrax bacillus is a defensive mechanism against bactericidal capacities in an infected animal. It is stated that capsulation renders the bacillus less susceptible to phagocytosis. In certain anti-anthrax sera precipitins for the bacilli are stated to be present, but the investigation of such sera by the complement deviation method has not furnished convincing evidence of the presence of anti-bodies.

Methods of Examination.—(*a*) *Microscopic Examination.*—In a case of suspected malignant pustule, film preparations should be made from the fluid in the vesicles or from a scraping of the incised or excised pustule, and stained by Gram's method. In this way practically conclusive evidence may be obtained. McFadyean's methylene-blue method (p. 335) should also be applied. Occasionally bacilli are so scanty that both film preparations made from different parts and even cultures may give negative results, and yet a few bacilli may be found when a section of the pustule is examined. Care ought to be taken in manipulating a pustule before excision, as, otherwise, the diffusion of the bacilli into the surrounding tissues may be aided. The examination of the blood in cases of anthrax in man usually gives negative results, with the exception of very severe cases, when a few bacilli may be found in the blood shortly before death.

(*b*) *Cultivation.*—The material should be stroked on agar tubes. At the end of twenty-four hours at 37° C. anthrax colonies will appear, and from their wavy margins can be readily recognised by means of a hand lens.

While the isolation of the b. anthracis from fresh material is usually easy, great difficulty may be encountered where the organism is to be sought for, in, say, a carcase which has been dead for from twenty-four to forty-eight hours, as the bacilli rapidly die out or are associated with putrefactive organisms. In such cases methods have been applied with a view to putting the organisms in specially favourable circumstances for growth and especially for sporulation; in one of these—the so-called Strassburg method—the suspected blood or tissue juice is spread on moist sterilised sticks of plaster of Paris and incubated in a moist chamber, and Müller and Engler have modified this by substituting for the plaster sterilised pieces of flower-pot placed under similar conditions.

(*c*) *Test Inoculation.*—A little of the suspected material mixed with some sterile bouillon or water should be injected subcutaneously into a guinea-pig or mouse. If anthrax bacilli are present, the animal usually dies within two days, with the changes in internal organs already described. The diagnosis of an organism as the anthrax bacillus cannot be said to be substantiated till its pathogenicity has been proved.

(*d*) *Ascoli's Thermo-precipitin Reaction.*—This depends on the observation that certain anthrax immune sera produce a precipitin reaction with the products of the b. anthracis. The suspected blood or tissue is boiled for a few minutes in five to ten volumes of normal saline

containing one part per thousand of acetic acid ; the fluid is cooled and filtered through paper or asbestos so as to obtain a clear filtrate ; a little of this is then run on to the top of the serum, and a white ring should form immediately at the junction of the fluids. The reaction sometimes occurs with normal sera, but in this case does not appear for a quarter of an hour. It is absolutely necessary that the serum to be used should be previously tested with material derived from an undoubted anthrax case, as only a certain small proportion of immune sera will give the reaction. The reaction seems to depend on an effect produced between the serum and substances derived from the bacilli, as it is most marked with tissues containing numerous organisms. It can be obtained with material which has been kept for six months, and numerous controls made with tissues of animals dying from other diseases are stated to have given negative results.

CHAPTER XV.

TYPHOID FEVER—BACILLI ALLIED TO THE TYPHOID BACILLUS.

Introductory.—The organism now known as the bacillus typhosus was first described in 1880–81 by Eberth, who observed its microscopic appearance in the intestinal ulcers and in the spleen in cases of typhoid fever (German, Abdominaltyphus). It was first isolated (from the spleen) in 1884 by Gaffky, and its cultural characters were then investigated. In 1885 Escherich described what is now known as the bacillus coli communis, which occurs in the normal intestine, and which both microscopically and culturally closely resembles the typhoid bacillus. While ordinarily the b. coli is a harmless saprophyte, under experimental conditions in animals and also naturally in man it may manifest pathogenic properties. These two bacilli belong to a widespread group of organisms isolated from various disease conditions, chiefly of the intestine, which bear close resemblances to one another, and whose differentiation is often a matter of considerable difficulty. Other members of this group are the para-typhoid bacilli, the dysentery bacilli, the b. enteritidis of Gaertner, the psittacosis bacillus, and the bacillus of hog cholera.

The general characters of the *coli-typhoid* group are as follows: the organisms, which are microscopically indistinguishable, are thin non-sporing bacilli, which in cultures often show variation in length; they are mostly motile, but this quality varies in different members; they possess flagella springing from all round the bacillus; they stain with ordinary dyes, and are all Gram-negative; they are all facultative anaerobes, *i.e.*, they grow best in the presence of oxygen, but can tolerate its absence; in growth characters on ordinary media they closely resemble one another, and they do not liquefy gelatin; they show wide differences in their actions on sugars, and a primary classification of the group is based on the fact that while b. coli produces acid and gas from lactose, none of the pathogenic

members have an effect on this sugar; in the ultimate differentiation of the organisms immunity reactions are of essential importance.

The Bacillus Coli Communis.

Bacillus Coli Communis.—*Morphological Characters.*—These are best seen in young bouillon or agar cultures. The bacillus is ordinarily from 2 to 4 μ long and about ·5 μ broad; longer forms up to 8 or 10 μ are not infrequent (Fig. 104). It is usually found to be motile, but the motility varies in different strains and under different growth conditions in the same strain. The organism may stain somewhat faintly with watery dyes, but is readily demonstrated with carbol-fuchsin (1 of the Ziehl-Neelsen stain in 20 of water); it is Gram-negative. In older cultures the bacillary protoplasm may be vacuolated and ballooned at the ends. By appropriate staining b. coli derived from cultures can be shown to possess flagella springing from all round the organism, varying in number and occasionally rather short.

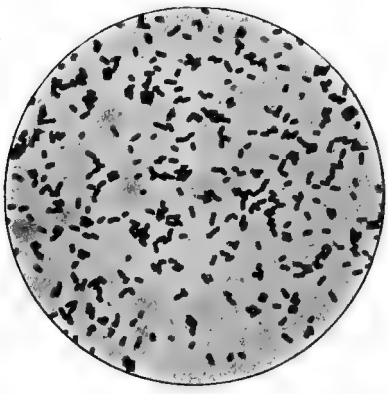

Fig. 104.—Bacillus coli communis. Film preparation from a young culture on agar. Stained with weak carbol-fuchsin. ×1000.

Culture Reactions on Ordinary Media.—The following are the appearances of the b. coli in the ordinary culture media:—

In *bouillon*, it produces a uniform turbidity. In stab cultures on *peptone gelatin* an abundant film-like growth takes place on the surface, and there is a whitish or brownish-white line along the stab without liquefaction of the gelatin. In sloped *agar tubes* a somewhat dense, glistening, white or brownish-white growth occurs along the stroke. On *agar plates* the surface colonies are somewhat large and, it may be, irregular in outline, but the deep colonies are smaller and lenticular in shape, and under a low power of the microscope appear rather dense to transmitted light. A similar growth occurs on *blood serum*. On *potatoes*, in forty-eight hours, there is a distinct film of

growth usually of a brownish tint, sometimes with a moist surface, which rapidly spreads and becomes thicker. The appearance on potato, however, varies much with the different strains and also with the reaction of the potato.

Culture Reactions on Special Media.—A great variety of media has been used for the appreciation of special characters in the b. coli. These reactions depend upon the capacities of the organism to orginate chemical changes in a variety of substances.

A. *Fermentative Reactions on Carbo-hydrates.*—B. coli shows great powers of splitting up carbo-hydrates with the formation of acids, especially lactic acid, and gases, chiefly carbon dioxide and hydrogen.

Fermentation of Sugars.—As stated on page 81, litmus or neutral-red peptone water, or dextrose-free bouillon in Durham's tubes is used, the sugar to be employed being added in the proportion of half to one per cent. The fermentative capacities of the b. coli are very wide. It produces acid and gas in lactose, glucose, lævulose, galactose, maltose, raffinose, mannite, dulcite, sorbite, and very frequently in cane sugar (saccharose).[1] It produces a similar change in the glucosides, salicin, and arbutin. In cultures in gelatin made from fresh meat sometimes bubbles of gas appear from the fermentation of the dextrose present in the meat (Fig. 108 C), and if melted gelatin be infected and shaken up, bubbles of gas form round the colonies developing at room temperature.

The reactions of b. coli in some media other than simple sugar solutions likewise depend on sugar fermentation, and of these are the following :—

Curdling of Milk.—If the b. coli be grown in milk, preferably litmus milk, acid is produced from the lactose present which further curdles the milk. If litmus milk be used, the acid reaction should be permanent when growth is allowed to go on for some days.

Measuring of Gas Formation.—As has been said, the gases produced by the b. coli in fermenting sugars are chiefly carbon dioxide and hydrogen. Many observers attach considerable importance, first, to the amount of gas formed from a given quantity of glucose in a given time, and, second, to the ratios of the two gases to one another, in such a fermentation. For the observation of this, MacConkey recommends the following method : fermentation tubes (p. 80, Fig. 32, *c*), with the closed limb graduated, containing 2 per cent. peptone and 1 per cent. glucose in tap water, are inoculated and incubated for forty-eight hours at 37° C. The tube is allowed to cool and the total amount of gas noted.

[1] A strain of b. coli fermenting cane sugar was formerly referred to as b. coli communior, but this differentiating term has been discarded.

The bulb is then filled with 2 per cent. sodium hydrate solution, the opening closed with the thumb and thoroughly shaken. After the gas has been collected in the closed arm the thumb is removed and the ratio of the hydrogen left to the original gas volume is read off.

Voges and Proskauer's Reaction.—This is a reaction which is not given by the classical type of b. coli, but as it occurs with many members of the coli group it may be described here. It also depends on carbo-hydrate fermentation. A glucose peptone solution tube is inoculated and incubated for three days. A solution of caustic potash is added and the tube allowed to stand for twenty-four hours at room temperature. A red fluorescent colour is produced, causing the medium to resemble a weak alcoholic solution of eosin.

B. *Action on Neutral-Red.*—When b. coli is grown on neutral-red lactose bouillon, a rosy red colour, the effect of the lactic acid upon the dye, is at first seen. Frequently this is succeeded by the appearance of a green fluorescence due to a direct action of the organism upon the dye. This is evidenced by the fact that the neutralisation of the lactic acid by an alkali does not lead to a reproduction of the original alkaline tint in the indicator. The degree of change, however, varies with composition of the medium, the important factors being the percentage of sugar, the reaction, and the strain of the bacillus used.

C. *Production of Indol.*—The b. coli produces indol in peptone water. The methods have been given on page 81, and for the detection of the reaction the use of Ehrlich's rosindol test is preferable (if the nitroso-indol test be used, a small quantity of a nitrite must be added). Two peptone tubes should always be inoculated, and if the reaction is not obtainable in one after two or three days' growth, the other should be incubated for from six to seven days and then tested. Where a faint reaction is obtained, it is well to corroborate the presence of indol by dissolving the rosindol out with amyl-alcohol as described.

D. *Reduction of Nitrates.*—The b. coli is frequently capable of reducing nitrates to nitrites. For this test, Savage recommends the use of a medium made by dissolving 10 grms. of peptone in 1 litre of ammonia-free distilled water, and adding 2 grms. of nitrite-free potassium nitrate. The medium is filtered, tubed, and sterilised for half an hour on three days. Tubes are infected and incubated for forty-eight hours, the formation of nitrites being now tested for by Ilosvay's method. The following solutions are required: (*a*) sulphanilic acid, ·5 grm. dissolved in 150 c.c. dilute acetic acid (s.g. 1·04); (*b*) 1 grm. α-naphthylamine is dissolved in 22 c.c. of water, the

solution filtered, and 180 c.c. dilute acetic acid added. In using the test, 2 c.c. of each of these solutions is added to 10 c.c. of culture. If reduction of the nitrates has occurred, a rose-pink colour should develop almost immediately. It is to be noted that the pink colour first produced sometimes disappears as it is formed or on shaking; in such a case further portions of the two reagents in equal quantities should be added.

Agglutination Reactions of the B. coli.—When the b. coli has produced a pathological condition in an animal, the serum of the infected animal frequently manifests specific agglutinative characters, especially towards the strain of the organism isolated from the lesions. Under certain circumstances, also, the serum of an animal infected by some other member of the b. coli group may also agglutinate strains of this organism. This subject will be treated of when we consider the differentiation of the members of the group one from another.

Isolation of the B. coli.—In the case of abscesses or coli infection of the kidney or bladder, etc. (p. 212), the isolation of the organism is easily accomplished by smearing the pus or urine on plates of MacConkey's lactose neutral-red agar (p. 49). When the organism is present along with other bacteria, as in the case of water, sewage, etc., this medium is also to be recommended, as the bile salts present tend to inhibit the growth of organisms except those belonging to the coli group. The media of Conradi-Drigalski, Fawcus, and Browning (pp. 49–51) are also useful; in these a similar inhibition is effected by certain aniline dyes, picric acid, etc. All these media have their uses, and it is best to select that with which the worker has had most experience. The methods of the application of these media and the appearances of b. coli have already been described (pp. 49–51).

The Recognition of typical B. coli.—The work on b. coli, especially in relation to its occurrence in water, has revealed the existence of a very large number of varieties of the organism. These differ from one another in the absence of one or more of the characters which may be elucidated by the application of the biological methods given. Considerable difference of opinion exists as to what characters are to be looked upon as type characters, *i.e.*, characters shared by the greatest number of varieties isolated. In this connection it is to be noted that as the b. coli was originally isolated from the human intestine, and as the detection of such intestinal bacteria outside the body constitutes a most important practical question, the inquiry for type characters is to a certain extent limited to an attempt

to arrive at the type most frequently present in the human intestine.

Two standards may be alluded to. First, that of an English Committee which reported in 1904 on the standardisation of methods for the bacterioscopic examination of water. According to this, the b. coli is a small, motile, non-sporing bacillus, capable of growing at 37° C., Gram-negative, never liquefying gelatin, producing clot and permanent acidity of milk within seven days at 37°, fermenting glucose and lactose, with, in both, acid and gas formation,—subsidiary points being the formation of indol, the formation of a thick yellowish-brown growth on potato, production of fluorescence in neutral-red, reduction of nitrates, and fermentation of saccharose. A similar American Committee looked upon the typical organism as a non-sporing bacillus, motile, fermenting dextrose-broth, with the formation, in the closed limb of the fermentation tube, of about 50 per cent. of gas, of which about one-third is carbon dioxide, causing acid and clot in milk in forty-eight hours, not liquefying gelatin, producing indol and reducing nitrates. These two standards differ in the fact that the English Committee lay less weight on indol formation and the reduction of nitrates.

It may be said that, in addition to the type characters, lactose-fermenters from the human intestine usually ferment saccharose and dulcite and have no effect on adonite, inulin, and inosite, and it may be, no influence on mannite.

Pathogenic Properties of the B. coli.—In man, the b. coli has been found as the only organism present in various suppurative conditions (see Chapter VII.), especially in connection with the intestine (*e.g.*, appendicitis) and about the urinary tract. In the latter, it is also responsible for catarrhal conditions in the pelvis of the kidney and in the bladder, these being more common in the female, and frequently presenting chronic characters. As a practical point, it may be said that the treatment of the latter by vaccines, especially when made from the strain isolated from the lesion, has sometimes been attended with success. The b. coli is also apparently the cause of some cases of summer diarrhœa (cholera nostras), of some cases of infantile diarrhœa, and of some food poisonings.

The Pathogenicity of the B. coli and its Relation to that of the Typhoid Bacillus.—Intraperitoneal injection in guinea-pigs is often fatal. Subcutaneous injection may result in local abscesses, and sometimes in death from cachexia. Sanarelli found that the b. coli isolated from typhoid stools was much more virulent than when isolated from the stools of healthy persons. He holds that the increase in virulence is due to the effect of typhoid toxins. This increased virulence of the

b. coli in the typhoid intestine makes it possible that some of the pathological changes in typhoid may be due, not to the typhoid bacillus, but to the b. coli. Some of the general symptoms may be intensified by the absorption of toxic products formed by it and by other organisms. All the evidence, however, points to the two bacilli being distinct species. Thus Sanarelli accustomed the intestinal mucous membrane of guinea-pigs to toxins derived from an old culture of the b. coli, by introducing day by day small quantities of the latter into the stomach. When a relatively large dose could be tolerated, it was found that the introduction in the same way of a small quantity of a typhoid toxin was still followed by fatal result. Pfeiffer also found that while the serum of convalescents from typhoid paralysed the typhoid bacilli, it had no more effect on similar numbers of b. coli than the serum of healthy men.

The Bacillus Typhosus.

Bacillus Typhosus.—*Microscopic Appearances.*—It is sometimes difficult to find the typhoid bacilli in the organs of a typhoid patient. The best tissues for examination are a Peyer's patch where ulceration has not yet commenced or where it is just commencing, the spleen, the liver, or a mesenteric gland. The spleen and liver are better than the other tissues named, as in the latter the presence of the b. coli is more frequent. The organisms may be demonstrated in films made from the organs, but for the proper observation of the arrangement of the bacilli in the tissues, paraffin sections should be stained in carbol-thionin-blue for a few minutes, or in Löffler's methylene-blue for one or two hours. The bacilli take up the stain somewhat slowly, and as they are also easily decolorised, the aniline-oil method of dehydration may be used with advantage (*vide* p. 98). In such preparations the characteristic appearance to be looked for is the occur-

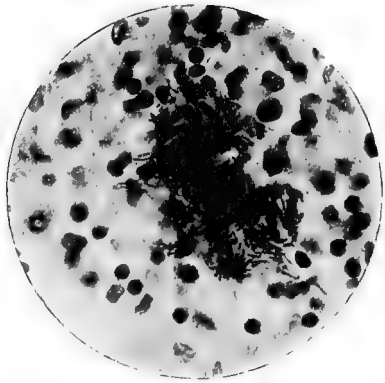

FIG. 105.—A large clump of typhoid bacilli in a spleen. The individual bacilli are only seen at the periphery of the mass. (In this spleen enormous numbers of typhoid bacilli were shown by cultures to be present in a practically pure condition.)
Paraffin section; stained with carbol-thionin-blue. ×500.

rence of groups of bacilli lying between the cells of the tissue (Fig. 105). The individual bacilli are 2 μ to 4 μ long, with somewhat oval ends, and ·5 μ in thickness. Sometimes filaments 8 μ to 10 μ long may be observed, though they are less common than in cultures. It is evident that one of the bacilli may frequently in a section be viewed endwise, in which case the appearance will be circular. This appearance accounts for some, at least, of the coccus-like forms which have been described. The bacilli are *Gram-negative.*

Isolation and Appearances of Cultures.—To grow the organism artificially it is best to isolate it from the spleen (for method, see p. 141), as it exists there in greater numbers than in the other solid organs, and may be the sole organism present even some time after death. Agar or MacConkey lactose plates may be employed. On the agar media the growths are visible after twenty-four hours' incubation at 37° C. On MacConkey plates the colonies are small, colourless, and dewdrop-like. On agar plates the superficial colonies are thin and film-like, circular or slightly irregular at the margins, dull white by reflected light, bluish-grey by transmitted light. Colonies in the substance of the agar are small, and appear as minute round points. Under a low objective, the surface colonies are found to be very transparent (requiring a small diaphragm for their definition), finely granular in appearance, and with a very coarsely crenated and well-defined margin. The deep colonies are usually spherical, sometimes lenticular in shape, and are smooth or finely granular on the surface, and more opaque than the superficial colonies. In cover-glass preparations, the bacilli are found to present the same microscopic appearances as in preparations from solid organs, except that there may be a greater number of the longer forms which may almost be called filaments (Fig. 106). Sometimes

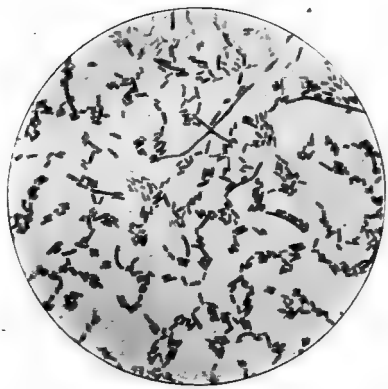

FIG. 106.—Typhoid bacilli, from a young culture on agar, showing some filamentous forms.
Stained with weak carbol-fuchsin. ×1000.

the diversity in the length of the bacilli is such as to throw doubt on the purity of the culture. As a general rule, in a young (twenty-four or forty-eight hours old) culture, grown at a uniform temperature, the bacilli are plump, and the protoplasm stains uniformly. In old cultures, or in cultures which have been exposed to changes of temperature, the protoplasm stains only in parts; there may be an appearance of irregular vacuolation either at the centre or at the ends of the bacilli.

FIG. 107.—Typhoid bacilli, from a young culture on agar, showing flagella. See also Plate III., Fig. 15.
Stained by Van Ermengem's method. × 1000.

Motility.—In hanging-drop preparations the bacilli are found to be actively motile. The smaller forms have a darting or rolling motion, passing quickly across the field, whilst some show rapid rotatory motion. The filamentous forms have an undulating or serpentine motion, and move more slowly. Hanging-drop preparations ought to be made from agar or broth cultures not more than twenty-four hours old. In older cultures the movements are less active.

Flagella.—On being stained by the appropriate methods

(*vide* p. 108), the bacilli are seen to possess many long wavy flagella which are attached all along the sides, and to the ends (Fig. 107). They are more numerous, longer, and more wavy than those of the b. coli.

Characters of Culture.—Generally speaking, on artificial media growths of the b. typhosus appear less dense than those of the b. coli. Stab cultures in *peptone gelatin* give a somewhat

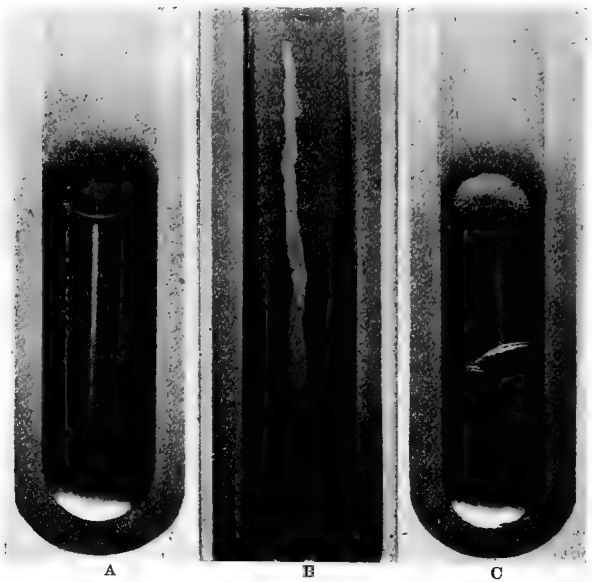

FIG. 108.

A. Stab culture of the typhoid bacillus in gelatin, five days' growth.
B. Stroke culture of the typhoid bacillus on gelatin, six days' growth.
C. Stab culture of the bacillus coli in gelatin, nine days' growth; the gelatin is split in its lower part owing to the formation of gas.

characteristic appearance. On the surface of the medium growth spreads outwards from the puncture as a thin leaf-like film or pellicle, with irregularly wavy margin (Fig. 108, A). It is semi-transparent and of bluish-white colour. Ultimately this surface growth may reach the wall of the tube. Not infrequently, however, the surface growth is not well marked. Along the stab there is an opaque whitish line of growth, of finely nodose appearance. There is no liquefaction of the medium. In stroke

cultures there is a thin bluish-white film, but it does not spread to such an extent as in the case of the surface growth of a stab culture (Fig. 108, B). In gelatin plates also the superficial and deep colonies present corresponding differences; on gelatin the surface colonies are rather more transparent than those on agar. Their characters, as seen under a low power of the microscope, also correspond. If a gelatin tube be inoculated and incubated at 37° C., a uniform turbidity is produced.

In stroke cultures on *agar* there is a bluish-grey film of growth, with fairly regular margins, but without any characteristic features. This film is moist, loosely attached to the surface, and can be easily scraped off.

The growth on *potatoes* is important. For several days (at incubation temperature) after inoculation there is apparently no growth. If looked at obliquely, the surface appears wet, and if it is scraped with the platinum loop, a glistening track is left: a cover-glass preparation shows numerous bacilli. Later, however, a slight pellicle with a dull, somewhat velvety surface may appear, and this may even assume a brown appearance. These characteristic appearances are only seen when a fresh potato with an acid reaction has been used.

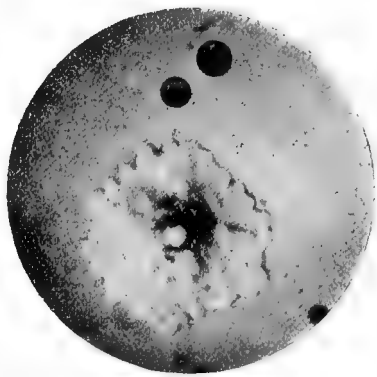

FIG. 109.—Colonies of the typhoid bacillus (one superficial and three deep) on a gelatin plate. Three days' growth at room temperature. ×15.

In *bouillon* incubated at 37° C. for twenty-four hours there is simply a uniform turbidity. Cover-glass preparations made from such sometimes show filamentous forms of considerable length without apparent segmentation.

Conditions of Growth, etc.—The optimum temperature of the typhoid bacillus is about 37° C., though it also flourishes well at the room temperature. It will not grow below 9° C. or above 42° C. Its powers of resistance correspond with those of most non-sporing bacteria. It is killed by exposure for half an hour at 60° C., or for two or three minutes at 100° C. Typhoid bacilli kept in distilled or in ordinary tap water

have usually been found to be dead after three weeks (Frankland).

Biological Reactions.—The growth of the typhoid bacillus on certain special media facilitates its being differentiated from the b. coli and the other members of the coli-typhoid group; its reactions in these media are largely negative. (See Table, p. 396).

The tests with sugars are important. The typhoid bacillus produces acid without gas in maltose, lævulose, glucose, and mannite, but originates no change in lactose, cane-sugar, or dulcite; in the last, however, acid formation may appear after some weeks. Further, there is no curdling of milk, although in litmus milk slight acid production occurs; in a time varying from a few days to a month the acid change may be succeeded by alkali production. Under ordinary circumstances, the typhoid bacillus is incapable of producing indol in peptone-salt solution, and does not alter neutral-red in lactose bouillon.

A great many special tests were formerly in use in differentiating the b. typhosus from the b. coli. The use of these is not now so necessary, but the following may be described:—

The Media of Capaldi and Proskauer.—The first of these ("No. 1") is a medium free of albumin, in which b. coli grows well and freely produces acid, while the typhoid bacillus hardly grows at all, and certainly will produce no change in the reaction. Its composition is as follows: asparagin ·2 parts, mannite ·2, sodium chloride ·02, magnesium sulphate ·01, calcium chloride ·02, potassium monophosphate ·2, distilled water to 100 parts. The second medium ("No. 2") contains albumin, and in it the b. coli produces no acid, while the typhoid bacillus grows well and produces an acid reaction. It consists of Witte's peptone 2 parts, mannite ·1, distilled water to 100 parts. After the constituents of each medium are mixed and dissolved, it is steamed for one and a half hours and then made neutral to litmus—the first medium, being usually naturally acid—by sodium hydrate, the second, being usually alkaline, by citric acid. The medium is then filtered, filled into tubes containing 5 c.c., and these are sterilised. After incubation for twenty hours the reaction of the infected medium is tested by adding litmus.

The identification of the typhoid bacillus is best facilitated by means of agglutination reactions which will be treated of later (p. 390).

The Pathology of Typhoid Fever.—The inflammation and ulceration in the *Peyer's patches and solitary glands of the intestine* are the central features. In the early stage there is an acute inflammatory condition, attended with extensive leucocytic emigration and sometimes with small hæmorrhages. At this period the typhoid bacilli are most numerous in the patches, groups being easily found between the cells. The

subsequent necrosis may be due to the action of the toxic products of the bacilli, which, however, gradually disappear, though they may still be found in the deeper tissues and at the spreading margin of the necrosed area. They also occur in the lymphatic spaces of the muscular coat. The number of the ulcers arising in the course of a case bears no relation to its severity. Small ulcers may occur in the lymphoid follicles of the large intestine.

The *mesenteric glands* corresponding to the affected part of the intestine are usually enlarged, sometimes to a very great extent, the whole mesentery being filled with glandular masses. In such glands there may be acute inflammation, and occasionally necrosis in patches occurs. Sometimes on section the glands are of a pale-yellowish colour, the contents being diffluent and consisting largely of leucocytes. Typhoid bacilli may be isolated both from the glands and the lymphatics connected with them, but the b. coli is in addition often present.

The *spleen* is enlarged,—on section usually of a fairly firm consistence, of a reddish-pink colour, and in a state of congestion. Of all the solid organs it usually contains the bacilli in greatest numbers. They can be seen in sections, occurring in clumps between the cells, there being no evidence of local reaction round them (Fig. 105). Similar clumps may occur in the *liver* in any situation, and without any local reaction. In this organ, however, there are often small foci of leucocytic infiltration, in which, so far as our experience goes, bacilli cannot be demonstrated. The bacillus is found, often in large numbers, in the gall-bladder, in which situation in cases which recover it may persist for years (*vide infra*). Clumps of bacilli may also occur in the *kidney*.

In addition to these local changes in the solid organs, there are also widespread *cellular degenerations* in the solid organs which suggest the action of toxic products.

In the *lungs* there may be bronchitis, patches of congestion and of acute broncho-pneumonia. In these, typhoid bacilli may sometimes be observed, but evidence of a toxic action depressing the powers of resistance of the lung tissue is found in the fact that the pneumococcus frequently occurs in such complications of typhoid fever.

The *nervous system* shows little change, though meningitis associated either with the typhoid bacillus, with the b. coli, or with the streptococcus pyogenes has been observed.

In typhoid fever the bacilli can in 90 per cent. of cases be isolated from the *blood* during the course of the illness. The bacilli have been found in the *roseolar spots* which occur in typhoid fever, but it cannot be yet stated that such spots are always due to the presence of the bacilli. The fact that the typhoid bacilli are usually confined to certain organs and tissues shows that they probably have a selective action.

The reaction of the body to the typhoid bacillus is markedly one of the lymphoid tissues. This is further evidenced by the blood cells, for while there is a leucopenia the lymphocytes are relatively increased in numbers. A successful reaction is accompanied by the appearance of bactericidal bodies in the serum.

The view of the development of the disease usually taken is that the bacilli, being ingested, multiply in the intestinal tract, cause inflammation and necrosis of the lymphoid tissue, and, gaining an entrance to the general circulation, produce the septicæmic phenomena which we have described.

Considerable attention has been attracted to another view of the course of infection put forward by Forster and his co-workers in Strasburg. According to this, the process is primarily a septicæmia, and the intestinal manifestations are looked on as secondary. The bacilli are supposed to gain entrance to the circulation possibly through the tonsils, sore throat being a not uncommon initial symptom of typhoid fever. In the blood they multiply, and, passing through the liver, gain access to the gall-bladder, set up a catarrhal inflammation there on the products of which they flourish, and thence pass out to infect the intestine. The intestinal lesions are either due to an elective action of bacteria brought by the blood, or come from infection by the bacilli which pass out from the gall-bladder—the former being apparently the alternative to which Forster leans. The evidence on which this view is based consists, firstly, in the results of animal experiments in which bacilli introduced intravenously have been subsequently found chiefly or solely in the gall-bladder—it may be, persisting there for weeks. Further, it is stated that bacilli can be isolated from the blood during the later parts of the incubation stage of the disease, and before they can be demonstrated in the intestine, where they are said not to appear until sometime during the first week of active disease. And again it is stated that in the bodies of persons dying from typhoid fever, while bacilli are always present in the gall-bladder and in the upper parts of the small intestine, they are frequently absent from the lower part of the latter and from the colon. It cannot be said that this view of the disease has been satisfactorily established. Opinion differs as to the alleged late appearance of the bacilli in the intestine, and the infectivity noticed during the incubation stage must be explained. Further, there is strong reason for believing that multiplication of the bacilli in the intestine can take place. The evidence of this rests on the finding of bacilli, it may be in considerable numbers, in the fæces and even in the blood of healthy individuals who have merely been in contact with typhoid cases or typhoid carriers, and who show no symptoms of the disease.

Suppurations occurring in connection with Typhoid Fever.—In a certain proportion of such suppurations the typhoid bacillus has been the only organism found. This has been the case in subcutaneous abscesses, in suppurative periostitis, suppuration in the parotid, abscesses in the kidneys, etc., and probably also in one or two cases of ulcerative endocarditis;

suppurations due to the typhoid bacillus may be of a very chronic and intractable nature. In the majority of cases other organisms, especially the b. coli and the pyogenic micrococci, have been obtained, the typhoid bacillus having been searched for in vain. It has, moreover, been experimentally shown, notably by Dmochowski and Janowski, that suppuration can be experimentally produced by injection in animals, especially in rabbits, of pure cultures of the typhoid bacillus, the occurrence of suppuration being favoured by conditions of depressed vitality, etc. These observers also found that when typhoid bacilli were injected along with pyogenic staphylococci, the former died out in the pus more quickly than the latter. Accordingly, in clinical cases where the typhoid bacillus is present alone, it is improbable that other organisms were present at an earlier date.

Occurrence of Gallstones in those who have suffered from Typhoid Fever.—As has been stated, foci of bacilli occur in the liver in typhoid fever, and these bacilli are excreted with the bile. In the gall-bladder they apparently not infrequently set up a catarrhal process in the biliary ducts and gall-bladder (*cholecystitis typhosa*), and are then in a better position for multiplication, in consequence of the presence of albuminous catarrhal secretions. There is evidence that the bacilli may persist in the gall-bladder for many years, and probably the catarrhal inflammation which they keep up is responsible for many of the cases of gallstones which occur—the albuminous matter produced causing a deposit of the bile in a solid form. Typhoid bacilli have actually been isolated from cases of gallstones operated on years after an attack of typhoid fever, and the bacilli have even been found within the calculi. They have also been demonstrated in chronic suppurations occurring in the gall-bladder. It is to be noted that gallstones are more frequently found in women than in men, the proportion being about four to one, and probably a considerable proportion of the total number of cases of gallstones are due to the previous occurrence of typhoid or paratyphoid fever.

Pathogenic Effects produced in Animals by the Typhoid Bacillus.—There is no disease of animals which is identical with typhoid, nor is there any evidence of the occurrence of the typhoid bacillus under ordinary pathological conditions in the bodies of animals. Attempts to communicate the disease to animals by feeding them on typhoid dejecta have been unsuccessful, and though pathogenic effects have been produced by introducing pure cultures in food, the disease has usually borne no resemblance to human typhoid. The results

of subcutaneous or intraperitoneal infection are no more satisfactory. Here pathogenic effects can easily be produced by the typhoid bacillus, but these effects are of the nature of a short acute illness characterised by pyrexia, rapid loss of weight, inability to take food, and frequently ending fatally in from twenty-four to forty-eight hours. The type of disease is thus very different from what occurs naturally in man. In such injection experiments the results vary considerably—no doubt due to the fact that different strains of the bacillus vary much in virulence. Ordinary laboratory cultures are often almost non-pathogenic. They can, however, be made virulent in various ways (see Chap. XXII.).

The Toxic Products of the Typhoid Bacillus.—Here very little light has been thrown on the pathology of the disease. There exist in the bodies of typhoid bacilli toxic substances which in artificial cultures do not pass to any great degree out into the surrounding medium; they have no specific effect. The bodies of bacteria killed by chloroform vapour are very toxic—more so than filtered cultures—and there is evidence of the release of poisons from the organisms when these undergo bacteriolysis in the animal body. Allan Macfadyen, by grinding up typhoid bacilli frozen solid by liquid air, produced a fluid whose toxic effect he attributed to the presence of the intracellular poisons.

The Immunisation of Animals against the Typhoid Bacillus.—Earlier observers had been successful in accustoming mice to the typhoid bacillus by the successive injections of small and gradually increasing doses of living cultures of the bacillus. Later, Brieger, Kitasato, and Wassermann found that the bacillus when modified by being grown in a bouillon made from an extract of the thymus gland no longer killed mice and guinea-pigs. These animals after injection were moreover immune, and it was also found that the serum of a guinea-pig thus immunised could, if transferred to another guinea-pig, protect the latter from the subsequent injection of a dose of typhoid bacilli to which it would naturally succumb. Chantemesse and Widal, Sanarelli, and also Pfeiffer, immunised guinea-pigs against the subsequent intraperitoneal injection of virulent living typhoid bacilli, by repeated and gradually increasing intraperitoneal or subcutaneous doses of dead typhoid cultures in bouillon. Experiments performed with serum derived from typhoid patients and convalescents indicate that similar effects occur in those who have successfully resisted the natural disease. The serum of such patients has *antibacterial* powers, but there is no evidence that it contains any *antitoxic* bodies

(see chapter on Immunity). Pfeiffer, for example, found on adding serum from typhoid convalescents to typhoid bacilli killed by heat, and injecting the mixture into guinea-pigs, that death took place as in control animals which had received these toxic agents alone. Pfeiffer also found that by using the serum of immunised goats, he could, to a certain extent, protect other animals against the subsequent injection of virulent living typhoid bacilli. On trying to use the agent in a curative way, *i.e.*, injecting it only after the bacilli had begun to produce their effects, he got little or no result.

General View of the Relationship of the B. typhosus to Typhoid Fever.—1. We see in typhoid fever a disease having its centre in and about the intestine, and acting secondarily on many other parts of the body. In the parts most affected there is always a bacillus present, which can be isolated from the characteristic lesions of the disease and from other parts of the body as described, and further, it is found by culture and serum reactions to differ from other organism. A bacillus giving all the reactions of the typhoid bacillus has never been isolated except from cases of typhoid fever, or under circumstances that make it possible for the bacillus in question to have been derived from a case of typhoid fever.

2. A difficulty in the way of accepting the etiological relationship of the b. typhosus lies in the comparative failure of attempts to cause the disease in animals. We have noted, however, that in nature animals do not suffer from typhoid fever.

3. The observations on the protective power against typhoid bacilli shown to belong to the serum of typhoid patients and convalescents, and the action of such serum in agglutinating the bacilli (*vide infra*), indicate an etiological relationship between the bacillus and the disease. Additional evidence is found in the fact that vaccination with the dead bacilli (*vide infra*) has a marked effect in preventing the disease from arising in those exposed to infection, and also in lowering the mortality when the fever attacks inoculated persons.

These facts constitute indirect but practically conclusive evidence of the causal relationship of the typhoid bacillus to the disease. Confirmation of this view is found in the fact that cases have occurred where bacteriologists have accidentally infected themselves by the mouth with pure cultures of the typhoid bacillus, and after the usual incubation period have developed typhoid fever. Several cases of this kind have been brought to our notice, and are not, we think, vitiated by the fact that other similar instances have occurred without the subsequent

development of illness. These latter would be accounted for by a low degree of susceptibility on the part of the individual or to a want of pathogenicity in the cultures.

There is evidence that certain individuals are relatively insusceptible to typhoid fever. The cases of the occurrence of typhoid bacilli in the healthy intestine support this view, and it has been further shown that during an epidemic certain persons may suffer from slight intestinal symptoms with typhoid bacilli in the fæces without the disease going through its usual course. The so-called "ambulatory" cases of typhoid fever form a link between these mild infections and fully developed typhoid fever.

Typhoid Carriers.—In the great majority of cases of typhoid fever, the bacilli disappear from the fæces within from two to ten weeks of convalescence, but in a certain proportion of cases, probably about 2 to 5 per cent., evidence is found of the persistence of the bacilli for many months, and in certain cases their existence has been demonstrated even thirty and, it may be, fifty years after the attack of illness. Carriers have been arbitrarily classified as "temporary" (*i.e.*, those excreting bacilli up to a year after an attack of fever) and as "chronic" (those where this period is exceeded), but the distinction is unimportant. It may be said that the majority of carriers to whom outbreaks have been traced are women. Persons in whom the carrier phenomenon is present are a constant danger to those around them, as the infectivity of the bacilli frequently remains, and during recent years the importance of such carriers has been recognised as explaining many outbreaks of the disease. The cases traceable to such an origin are of the type usually classed as sporadic. They arise amongst persons associated with carriers, especially when the latter are concerned in the preparation of food. From time to time, however, larger epidemics have arisen from a carrier having contaminated a milk supply in a dairy. The site of the multiplication of the bacteria in a great many of these carriers is probably the gall-bladder (see p. 367). As has been stated, the typhoid bacilli may persist there for many years, often giving rise to gallstones. The fact that women appear to be more liable to gallstones than men constitutes a serious factor in relation to the problem of the typhoid carrier, as women are more concerned in the preparation of food. An additional danger lies in the fact that carriers usually appear to be in perfect health or may only suffer from slight, and to them unimportant, pains in the region of the gall-bladder, it being well known that in only a proportion of patients suffering from gallstones do severe symptoms arise. An additional factor

in the carrier problem lies in the fact stated above, that apparently certain persons ingest the typhoid bacilli, and the latter may multiply for some months in the intestinal tract without giving rise to typhoid fever. Such persons have been referred to as "paradoxical" carriers; they represent those who either are naturally insusceptible to typhoid fever or who have developed immunity in consequence of a previous attack; they may constitute a danger to susceptible persons with whom they may come in contact. The most serious danger to a community arises, however, from the "chronic" carrier. In certain carriers, the focus of multiplication of the typhoid bacillus may not be the bowel but the kidney or bladder, the bacilli in such cases passing out in the urine.

The tracking down of a typhoid carrier constitutes an important and difficult problem. Firstly, the serum of all suspicious persons ought to be subjected to the Widal test (*vide infra*). Usually speaking, the carrier gives a positive reaction, but sometimes this is absent and sometimes is only obtained with a low dilution of the serum. Further, it has been shown in chronic carriers that the agglutinating capacity of the serum varies from time to time and sometimes may be absent. The proof of a person being a carrier lies essentially in the isolation of the typhoid bacillus from the fæces or the urine, and it is to be noted that, especially in the former, the organism is not constantly present,—in certain cases months of remission have been recorded. Several explanations have been advanced to account for the facts observed, such as the occurrence of symptomless reinfections or of periodic more or less acute auto-infections from a latent focus of persistence of the bacterium in, *e.g.*, the gall-bladder. In any case, the necessity for repeated investigation of a suspected carrier is obvious. The methods to be adopted are detailed on p. 389. Much work has been directed to the question of freeing the typhoid carrier from the organism, but although various methods, such as intestinal antisepsis, vaccination, excision of the gall-bladder, have been tried, success has hitherto not been attained. From the public health standpoint, the prevention of carriers from occurring in a population must be provided for, and in fever hospitals means ought to be taken for retaining convalescents from typhoid until the bodily discharges are free from the typhoid bacillus. This is now widely practised.

The Epidemiology of Typhoid Fever.—In civilised communities the prevalence of typhoid fever has been very markedly reduced, coincident with the substitution of central filtered water supplies for well waters and with the improvements effected in

general sanitation and especially in the rapid removal of refuse. In certain localities, however, there are still periodic outbreaks, often of a seasonal character, and it has been customary to attribute these largely to the capacity of the typhoid bacillus to live for long periods and to multiply outside the human body. The investigation of the prevalence of the typhoid bacillus under saprophytic conditions is a matter of great difficulty, as for its proper study the capacity of the organism to multiply in the presence of other intestinal and putrefactive organisms constitutes the essential problem. There is no doubt that the bacillus can remain viable under such circumstances for some days and it may be for weeks. The existence of carriers in all communities where typhoid fever occurs has, however, thrown new light on the subject and has accounted for the origin of many outbreaks otherwise obscure. There is now some doubt whether the prolonged viability of the typhoid bacillus under saprophytic conditions plays such an important part in the incidence of the disease as has hitherto been supposed. In many cases survival outside the body for a considerable time is an essential factor where a water or food supply becomes infected with material derived from a carrier. At the present time small outbreaks of the disease frequently originate in those who are brought into domestic contact with carriers, and larger epidemics originate when a carrier pollutes a water or especially a milk supply. During such outbreaks secondary cases may arise in persons infected not from the primary source but from contact with patients primarily infected. It cannot be said, however, that the seasonal incidence of typhoid fever has been elucidated, and this is especially true of the isolated cases occurring about the same time in large communities in persons unconnected with each other and whose contact with a carrier cannot be traced. In certain cases it has been supposed that flies constitute a factor in the prevalence of the disease by infecting food after having been in contact with garbage, but the evidence here is unconvincing.

The Serum Diagnosis of Typhoid Fever.—This method of diagnosis is based on the fact that living and actively motile typhoid bacilli, if placed in the diluted serum of a patient suffering from typhoid fever, within a very short time lose their motility and become aggregated into clumps.

The relation of the *dilution of the serum* to the occurrence of clumping is most important. The general consensus of opinion, with which our own experience agrees, is that when a serum in a dilution of 1 : 30 causes complete clumping in half an hour,

it may safely be said that it has been derived from a case of typhoid fever, provided that the patient has not been inoculated against typhoid, and has not previously suffered from the disease. Suspicion should be entertained as to the diagnosis if a lower dilution, or if a longer time is required.

The methods by which the test can be applied have already been described (p. 116).

(1) It will be there seen that the loss of motility and clumping may be observed microscopically. If a preparation be made by the method detailed (typhoid serum in a dilution of, say, 1 : 30 having been employed), and examined at once under the microscope, the bacilli will usually be found actively motile, darting about in all directions. In a short time, however, these movements gradually become slower, the bacilli begin to adhere to one another, and ultimately become completely immobile and form clumps by their aggregation. When this occurs the reaction is said to be complete. If the clumps be watched still longer a swelling up of the bacilli will be observed, with a granulation of the protoplasm, so that their forms can with difficulty be recognised. In a preparation similarly made with non-typhoid serum the individual bacilli can be observed separate and actively motile.

(2) A corresponding reaction visible to the naked eye is obtained by the "sedimentation test," the method of applying which has also been described (p. 118). The test in this form has the disadvantage of taking longer time than the microscopic method, but it is useful as a control ; in nature it is similar.

Such is what occurs in the case of a typical reaction. The value of the method as a means of diagnosis largely depends on attention to several details.

The *race of typhoid bacillus* employed is important. All races do not give uniformly the same results, though it is not known on what this difference of susceptibility depends. A race must therefore be selected which gives the best result in the greatest number of undoubted cases of typhoid fever, and which gives as little reaction as possible with normal sera or sera derived from other diseases. This latter point is important, as some races react very readily to non-typhoid sera. Again, care must be taken as to the *state of the culture* used. The suitability of a culture may be impaired by varying the conditions of its growth. Continued growth of a race at 37° C. makes it less suitable for use in the test, as the bacilli tend naturally to adhere in clumps, which may be mistaken for those produced by the reaction. Wyatt Johnson recommended that the stock culture should be kept growing on agar at room temperature and maintained by agar sub-cultures made once a month. For use in applying the test, bouillon sub-cultures are made and incubated for twenty-four hours at 37° C.

The reaction given by the serum in typhoid fever usually begins to be observed about the seventh day of the disease, though occasionally it has been found as early as the fifth day, and sometimes it does not appear till the third week or later. Usually it becomes gradually more marked as the disease advances, and it is still given by the blood of convalescents from typhoid, but cases occur in which it may permanently disappear before convalescence sets in. How long it lasts after the end of the disease has not yet been fully determined, but in many cases it has been found after several months or longer. As a rule, up to a certain point, the reaction is more marked where the fever is of a pronounced character, whilst in the milder cases it is less pronounced. In certain grave cases, however, the reaction has been found to be feeble or almost absent. In some cases, which from the clinical symptoms were almost certainly typhoid, the reaction has apparently been found to be absent. Such cases should always be investigated, from the point of view of their possibly being due to other intestinal infections.

It has been found that the reaction is not only obtained with living bacilli, but in certain circumstances also with bacilli that have been killed by heating at 60° C. for an hour—if a higher temperature be used, sensitiveness to agglutination is impaired. Dreyer has introduced a simple technique which enables an ordinary practitioner provided with dead cultures to carry out the test for himself. For this the standard cultures (p. 118) are used.

Besides the blood serum, it has been found that the reaction is given in cases of typhoid fever by pericardial and pleural effusions, by the bile and by the milk, and also to a slight degree by the urine. The blood of a fœtus may have little agglutinating effect, though that of its mother may have given a well-marked reaction; sometimes, however, the fœtal blood gives a well-marked reaction. It may here also be mentioned that a serum will stand exposure for an hour at 58° C. without having its agglutinating power much diminished. Higher temperatures, however, cause the property to be lost. It is sometimes necessary to heat the serum to 55° C. for thirty minutes before testing for agglutination as bacteriolytic substances may be present; such heating destroys the complement concerned in the lytic action (see Chapter IV.).

With regard to the value of the serum reaction there is little doubt. In nearly 95 per cent. of cases of typhoid it can be obtained in such a form that no difficulty is experienced if the precautions detailed above are observed. The causes of possible error may be summarised as follows: The serum of the person

may naturally have the capacity of clumping typhoid bacilli; there may have been an attack of typhoid fever previously with persistence of agglutinative capacity; the case may be one of disease caused by an allied bacillus; the disease may have a quite different cause, and yet the serum may react with typhoid bacilli; the disease may be typhoid fever and yet no reaction may occur. The most important of these sources of error is that with which diseases caused by allied organisms are concerned (see p. 390). The very wide application of the reaction has elicited the fact that it is given in many cases of slight, transient, and ill-defined febriculæ, which occur especially when typhoid fever is prevalent. Some of these may be aborted typhoid, some may be paratyphoid. There is no doubt that, if all the facts are taken into account, the cases where the reaction gives undoubtedly correct information so far outnumber those in which an error may be made that it must be looked on as a most valuable aid to diagnosis.

The Agglutination of Organisms other than the B. typhosus by Typhoid Serum.—Though many races of the b. coli give no reaction with a typhoid serum, there are others which react positively. Usually, however, a lower dilution and a longer time are required for a result to be obtained, and the reaction is often incomplete. It has also been found that other organisms belonging to the coli-typhoid group react in a similar way. The important point here is the determination of the highest dilution with which clumping is obtained (see p. 392, and for methods, see p. 390). There is a point in this connection regarding which further light is required. Many races of b. coli in use have been isolated from typhoid cases, and we as yet do not know what effect this circumstance may have on its subsequent sensitiveness to agglutination by typhoid serum. Again, Christophers has pointed out that a large proportion of sera from normal persons or from those suffering from diseases other than typhoid will clump the b. coli in dilutions of from 1 : 20 to 1 : 200, and no doubt many of the reactions shown by typhoid sera towards b. coli are due to the pre-existence in the individuals of an agglutinative property towards the latter bacillus.

Vaccination against Typhoid.—The principles of the immunisation of animals against typhoid bacilli have been applied by Wright and Semple to man for prophylactic purposes. The method of preparing the vaccine has been described on p. 131. Two doses are usually given separated by an interval of ten days. The first consists of 500,000,000 bacilli and the second of 1,000,000,000. The effects of the first injection are some tenderness locally and in the adjacent lymphatic glands, and it may be local swelling, all of which come on in a few hours, and may be accompanied by a general feeling of restlessness and a rise of temperature, but the illness is over in twenty-four

hours. During the next ten days the blood of the individual begins to manifest, when tested, an agglutination reaction, and further, Wright has found that usually after the injection there is a marked increase in the capacity of the blood serum to kill the typhoid bacillus *in vitro*. The second injection usually produces practically no symptoms, but ought to be followed by a further rise in agglutinins in the serum. These observations, there is little doubt, indicate that the vaccinated person possesses a degree of immunity against the bacillus, a conclusion borne out by the results obtained in the use of the vaccine as a prophylactic against typhoid fever. Extensive observations were made in the British army in India, and in the South African War the efficacy of the treatment was put to test. Though in isolated cases not much difference is observed among those treated as compared with those untreated, yet the broad general result is that on the one hand protective inoculation diminishes the tendency for the individual to contract typhoid fever, and, on the other, if the disease be contracted, the likelihood of its having a fatal result is diminished. Thus, in India, of 4502 soldiers inoculated, ·98 per cent. contracted typhoid, while of 25,851 soldiers in the same stations who were not inoculated, 2·54 per cent. took the disease. In Ladysmith during the siege there were 1705 soldiers inoculated, among whom 2 per cent. of cases occurred, and 10,529 uninoculated, among whom 14 per cent. suffered from typhoid. Wright collected statistics dealing in all with 49,600 individuals, of whom 8600 were inoculated, and showed a case incidence of 2·25 per cent., with a case mortality of 12 per cent.; in the remaining 41,000 uninoculated the case incidence was 5·75 per cent. and the case mortality 21 per cent. The best results are obtained when ten days after the first inoculation, as recommended above, a second similar inoculation is practised. Wright found that in certain cases immediately after inoculation there was a fall in the bactericidal power of the blood (negative phase), and he is of opinion that this indicates a temporary increased susceptibility to the disease. He therefore recommends that when possible the vaccination should be carried out some time previous to the exposure to infection. The deductions originally made have been amply confirmed during the present war, and the method has been extended by using a vaccine which protects not only against typhoid fever but also against the paratyphoid infections (*v. infra*).

Vaccine Treatment of Typhoid Fever.—As in the case of other acute infections, vaccines have been used in the treat-

ment of typhoid fever during the acute stage (Leishman and Smallman). The method is to inject hypodermically 100 million dead typhoid bacilli, *i.e.*, a fifth of the first dose used for the protective inoculation. If the temperature shows a tendency to fall, this may be repeated about every four days. Experience as to the success of the treatment varies, but the results obtained are hopeful and justify the method being further applied.

Antityphoid Serum.—Chantemesse immunised animals with dead cultures of the typhoid bacillus, and, having found that their sera had protective and curative effects in other animals, used such sera in human cases of typhoid with apparent good result. In the hands of others, however, such a line of treatment has not been equally successful.

Isolation of the Typhoid Bacillus from Water Supplies.—A great deal of work has been done on this subject, and the b. typhosus has been isolated from water during epidemics, though the difficulties are very great. The b. coli is, as might be expected, the organism most commonly present in such circumstances. In the case of both bacteria, the whole series of culture reactions must be gone through before any particular organism isolated is identified as the one or the other; probably there are saprophytes existing in nature which only differ from them in one or two reactions. In examining waters, the MacConkey or similar media may be employed with advantage. Klein filtered a large quantity through a Berkefeld filter, and, brushing off the bacteria retained on the porcelain, made cultures. A much greater concentration of the bacteria was thus obtained. From time to time various substances have been used with the object of inhibiting the growth of the b. coli without interfering with that of the b. typhosus. Most of these have not stood the test of experience. Caffeine has been used for this end. For use in examining waters the following is the method employed: To 900 c.c. of the suspected water there are added 10 grms nutrose dissolved in 80 c.c. of sterile water, and 5 grms. of caffeine dissolved in sterile distilled water, heated to 80° C. and cooled to 55° C. before addition. After mixing the ingredients, there is added 10 c.c. of ·1 per cent. crystal violet. The flask is incubated at 37° C. for twelve hours, and then plates of Conradi-Drigalski medium are inoculated from it. On the whole there is little to be gained from this attempt to isolate the typhoid bacillus from water in any particular case, and it is much more useful for the bacteriologist to bend his energies toward the obtaining of the indirect evidence of contamination of water by sewage, to the nature of which attention has been called in Chapter V.

Paratyphoid Fever.

In 1898 Gwyn recorded a case clinically resembling typhoid fever, from the blood of which he isolated an organism then known as the paracolon bacillus and which is now denominated the bacillus paratyphosus. Since that time numerous outbreaks of intestinal disease have been described associated with the occurrence in the stools and in the blood of organisms of this variety. During the present war these have come into

great prominence from the fact that they have constituted a predominant group amongst intestinal infections as a whole. Clinically they generally have the character of a mild typhoid infection, often characterised merely by a transient illness, and the mortality in such cases does not amount to more than 4 per cent. Pathologically the lesions are those of typhoid fever with or without ulceration, but there seems to be a greater tendency to diffuse follicular inflammations and infections of the large intestine and of the appendix and to the occurrence of peritonitis without perforation and of suppuration in, *e.g.*, the spleen, brain, kidney, lymphatic glands, etc. It has been suggested that initially the old term "enteric fever" or "enterica" should be applied to all clinical cases of a typhoid type pending their differentiation into typhoid and paratyphoid fevers by bacteriological methods. It will be seen below that the latter involve a further differentiation between enterica and bacillary dysentery, and that the existence of two varieties of the paratyphoid bacillus must be taken into account.

The Paratyphoid Bacilli.—These organisms have the general characters of the coli-typhoid group, motility being usually active though the flagella are often few in number. They are non-lactose fermenters and originate acid and gas in glucose, mannite, maltose, dulcite, lævulose, galactose, sorbite, and arabinose; they do not ferment raffinose, saccharose, salicin, or inulin. Of these reactions, that towards lactose differentiates them from b. coli, and the production of acid and gas in mannite distinguishes them from b. typhosus and b. dysenteriæ. They do not produce indol. Two varieties occur, denominated respectively "paratyphoid A" and "paratyphoid B," the latter being the commoner. The fermentative capacities of these are identical, but A is the less active—gas formation being often scanty and late in appearance. They present slight differences on ordinary media. On gelatine, agar, and potato A in its growth rather resembles b. typhosus, while B is more like b. coli; in litmus milk A produces slight permanent acidity, while, in the case of B, after the third day acidity gives place to alkalinity. In the ultimate differentiation of the two types their capacity of originating specific agglutinating sera is of greatest importance.

The b. paratyphosus was originally isolated from suppurative conditions, *e.g.*, of the genito-urinary tract, of bone, of the thyroid, etc.; several of these probably followed an intestinal condition—the tendency to suppuration as a complication or sequel to such infection being now recognised. Illnesses of the

enteric type constitute the commonest paratyphoid infections of man, and originate, as in the case of true typhoid, through the bacilli gaining entrance by the mouth. The intestinal lesions are the most manifest effects of the organisms, which occur in large numbers in the stools; their presence in the blood also, especially in B infections, is a marked feature—even more so than in typhoid fever, and they have also been isolated from the skin eruptions. They persist in the intestine during convalescence, and paratyphoid carriers have been recorded. Paratyphoid infections are found all over the world; in India and Sumatra cases of paratyphoid A infections with relatively few intestinal symptoms have been recorded as of relatively frequent occurrence. The illness here lasts from nine to fourteen days and is characterised by headache, pains in the neck and loins, fever, occasionally by diarrhœa, bronchitis, and a rash (sometimes morbilliform); and usually it is non-fatal. Gall-bladder infections with b. paratyphoid A are common.

In animals the paratyphoid bacilli have pathogenic effects similar to those of the b. typhosus—septicæmic and pyæmic manifestations rather than intestinal conditions being originated.

As in typhoid fever patients suffering from paratyphoid develop specific agglutination phenomena in their blood serum through the organism (be it A or B) with which they are infected. This is not only of importance in relation to diagnosis but is also evidence of the causal relationship of the organism to the disease. With paratyphoid B when a patient's serum in a dilution of 1 in 25 agglutinates the organism a positive diagnosis may be made; with paratyphoid A the amount of agglutinins formed may be less and here many experienced observers give a positive diagnosis when agglutination is obtained with a serum diluted 1 in 10. In using such data for diagnostic purposes the previous preventive inoculation of the patient with paratyphoid bacilli must be excluded.

Further points regarding the agglutination of these organisms (p. 390) and the methods of isolation (p. 388) will be treated later.

Preventive Inoculation.—All the evidence points to inoculation with the b. typhosus having no effect in protecting against paratyphoid fever. It is therefore now customary, when exposure to both infections is anticipated, to use for the inoculation a mixture containing in the dose 500 million b. typhosus, 250 million b. paratyphosus A, and 250 million b. paratyphosus B—two doses (the second being double the first) being given at the same interval as with the original typhoid vaccine.

Organisms associated with Food Poisoning and Kindred Bacilli.

Organisms of the paratyphoid group—sometimes apparently the paratyphoid bacilli themselves—are the agents at work in the great majority of the not infrequently occurring cases of illness usually described as "food poisoning."[1] Such poisoning is often referred to as "ptomaine poisoning," from the idea originally prevailing that the symptoms were caused by alkaloidal substances produced during putrefactive processes occuring in meat. Certain cases of illness arising within an hour or two of the taking of tainted meat may be due to the presence of poisons, but in the great majority of single or multiple cases of illness traceable to food the symptoms do not appear so rapidly, and are associated with the multiplication in the intestine of organisms of the type now under consideration, and it may be also with an infection of the blood. In such cases, the meat at fault may not, to taste or smell, present any unusual features, but very often there can be isolated from it an organism identical with organisms derived from the sick individuals. Sometimes it has been proved that the animals from which the meat was derived have been suffering from illnesses probably due to the organisms subsequently found, but this has not always been the case, healthy meat being here contaminated by contact with infective matter. The foods giving rise to poisoning usually belong to the preserved food class, or consist of sausages or similar products, but cases also arise from infected milk. There is every reason to believe that the organisms in question may not be killed in the ordinary processes of cooking, in which the internal parts of the meat may not reach the temperature of blood coagulation. The following are the chief organisms concerned:—

Bacillus Enteritidis (Gaertner).—In 1888, Gaertner, in investigating a number of cases of gastro-enteritis resulting from eating the flesh of a diseased cow, isolated, from the meat and from the spleen of a man who died, a bacillus which is now known to have been morphologically and culturally indistinguishable from the b. paratyphosus. Since then, in a great number of similar outbreaks, similar bacilli have been found both in the stools and in the organs. The cultural characters are those of the group, and it can be isolated by the technique applicable to the kindred bacilli. The organism can

[1] A special type of food poisoning is associated with the *Bacillus botulinus*, *q.v.*

only be differentiated by agglutination reactions. It has also been found that the serum of persons suffering from meat poisoning sometimes clumps the typhoid bacillus, though a higher concentration is required than in the case of Gaertner's bacillus. The Gaertner group of organisms is very pathogenic for laboratory animals. Often, whatever the channel of infection, there is intense hæmorrhagic enteritis, and very usually there is a septicæmia with the occurrence of serous inflammations; the bacilli are recoverable from the solid organs and often from the blood. In man, as the name of the bacillus indicates, the symptoms are centred in the intestine, where there is usually marked inflammation of the mucous membrane, sometimes attended with hæmorrhage into it; evidence of a septicæmic condition may also exist. Infection may take place by the bacillus itself, and here the illness usually appears within twenty-four hours of the food being partaken of, but symptoms may appear almost at once, in which case they are no doubt due to the action of toxins; here it is important to note that the poisons formed by this group of organisms are relatively heat-resisting, so that boiling for a time does not destroy the toxicity. It is stated that the b. Gaertner occasionally occurs in normal fæces.

The **Bacillus Suipestifer** (or Ærtryck) was isolated from cases of hog-cholera, though the pathology of this disease is very obscure and it is usually attributed to a filter-passer. The organism has been found in the intestine of normal pigs and may originate meat poisoning, especially where pork is the substance at fault. It has the common characteristics of the group and can only be distinguished from other members by serological methods. It shows specially close resemblances to b. paratyphosus B, and to differentiate it from this organism the method of absorption or that of complement fixation must be employed.

The Psittacosis Bacillus.—When parrots are imported from the tropics in large numbers, many may die of a septicæmic condition in which an enteritis, it may be hæmorrhagic, is a marked feature. There is intense congestion of all the organs and peritoneal ecchymoses. From the spleen, bone marrow, and blood there has been isolated a bacillus having the group characters, except that here also an effect on lactose has been described. The parrot is most susceptible to its action, but it also causes a fatal hæmorrhagic septicæmia in guinea-pigs, rabbits, mice, pigeons, and fowls, the bacilli after death being chiefly in the solid organs. From affected parrots the disease appears to be readily communicable to man, chiefly, it is probable, from the feathers being soiled by infective excrement. Several small epidemics have been recognised and investigated in Paris. After about ten days' incubation,

headache, fever, and anorexia occur, followed by great restlessness, delirium, vomiting, often diarrhœa, and albuminuria. Frequently broncho-pneumonia supervenes, and a fatal result has followed in about a third of the cases observed. The organism has been isolated from the blood of the heart. The psittacosis bacillus is evidently one of the typhoid group, a fact which is further borne out by the observation that it may be clumped by a typhoid serum. The clumping is, however, said often to be incomplete, as the bacilli between the clumps may retain their motility. It differs from the typhoid bacillus in its growth on potato in agglutination reactions and in its pathogenicity.

Danysz's Bacillus and Rat Viruses.—Danysz isolated from an epizootic in field mice an organism of this group, which he introduced for the purpose of killing rats by originating in them through feeding a similar epizootic, and several viruses of this kind are in commercial use for this purpose. These have been investigated by Bainbridge, who, however, finds that they owe any efficiency they possess to the bacillus ærtryck and the bacillus enteritidis of Gaertner. The efficacy of such agents varies, and the mortality in artificially originated epizootics is from 20 to 50 per cent. Sometimes, apparently under natural conditions, rats develop an immunity to those viruses, and it is doubtful whether they are entirely innocuous to other animals which may partake of the food containing them.

Bacillary Dysentery.

Dysentery has for long been recognised as including a number of different pathological conditions, and within more recent times amœbic and non-amœbic forms have been distinguished. Of the latter, bacteria have been believed to be the causal agents, and an organism described by Shiga in 1898 has been established as the cause of a large proportion of cases. Shiga's observations were made in Japan, and confirmatory results have been obtained by Kruse in Germany, by Flexner and by Strong and Harvie in the Philippine Islands, and by Vedder and Duval in the United States. It is now further recognised that the epidemics of dysentery which from time to time occur in lunatic asylums are usually due to bacilli of this type, and in America the organism has been demonstrated in summer diarrhœa in children. Bacillary dysentery has been one of the most serious intestinal infections of the present war. The evidence for the relationship of the organism to the disease consists chiefly in its apparently constant presence in the dejecta in this form of dysentery, and in the agglutination of the organism by the serum of patients suffering from the disease, but confirmatory evidence has also come from animal experimentation and from the effects of anti-sera prepared by means of the bacilli. From different epidemics a great many different strains of the dysentery bacillus have been obtained, but these possess common characters and are closely related to

one another. The various strains resolve themselves into two chief groups, whose differences lie in their behaviour towards certain sugars, in their capacities of forming indol, and in their agglutinating reactions. The relation of amœbæ to dysentery will be discussed in the Appendix.

Bacilli of Dysentery. — The following are the characters common to the group :—

Morphological Characters. — The bacillus morphologically closely resembles the typhoid bacillus, but is on the whole somewhat plumper, and filamentous forms are comparatively rare. Involution forms sometimes occur, especially in glucose agar. The organism is non-motile. Vedder and Duval have, however, demonstrated in the case of one strain the presence of numerous lateral flagella, which are of great fineness, but of considerable length. No spore formation occurs; the organism is stained readily by the ordinary dyes, but is decolorised by Gram's method.

Cultural Characters.—In *gelatin* a whitish line of growth occurs along the puncture, but a superficial film-like growth is usually absent, or at least poorly marked. In plate cultures the superficial growths have often the vine-leaf contour of typhoid colonies, but they are more slimy. On *agar*, growth occurs as a smooth film with regular margins, but after two or three days, especially if the surface be moist, Vedder and Duval describe an outgrowth of lateral offshoots on the surface of the medium. On agar plates the colonies resemble those of the typhoid organism, being of smaller size and less opaque than those of the bacillus coli.

In *peptone bouillon* a uniform haziness is produced. In *litmus milk* there is developed at first a slight degree of acidity, which is followed by a phase of increased alkalinity; no coagulation of the milk ever occurs. On *potato* the organism forms a transparent or whitish layer, which, however, in the course of a few days assumes a brownish-red or dirty grey colour, with some discoloration of the potato at the margin of the growth. As has been indicated, different strains of the bacillus behave differently towards different *sugars*. Without going into the question of the particular strains to be placed in the two groups, we may say that, roughly, these may be classified into the Shiga-Kruse group and the Flexner group. All produce acid in peptone-glucose and in taurocholate peptone-glucose; none produce change in lactose. The Shiga group ferment glucose only, while the Flexner group in addition produce acid in maltose or mannite, and the former do not

produce *indol*, while the latter do. Forms intermediate between the two groups occur, and special attention has been directed to a "Y" strain which does not ferment maltose. There is never any evolution of gas observed in sugar media. The variants of the dysentery bacillus group themselves chiefly round the Flexner type, from which they are more difficult to differentiate than from the Shiga type.

Relation to the Disease.—The organism has been found in large numbers in the dejecta, especially in the acute cases, where it may be present in almost pure culture. In Shiga's original observations on thirty-six cases examined, he obtained his bacillus in thirty-four from the dejecta, and in the two others post-mortem from the intestinal mucous membrane. The organism does not appear to spread deeply or to invade the general circulation. In the more chronic cases it may be difficult to obtain, on account of the large number of the bacillus coli and other bacteria present. Vedder and Duval found agar plates to be the best method of culture, these being incubated at the blood temperature. They also found that if the colonies which appeared at twelve hours were marked with a pencil, there was a greater probability of obtaining the bacillus of dysentery from those which appeared later, most of those appearing early being colonies of the bacillus coli. MacConkey's agar medium with lactose added may be used for isolation from stools. As the b. dysenteriæ is not a lactose fermenter, the colourless colonies which develop after twenty-four hours are picked out for further investigation.

As already stated, both acute and chronic cases are marked by the presence of this organism. In the former, where death may occur in from one to six days, the chief changes, according to Flexner, are a marked swelling and corrugation of the mucous membrane, with hæmorrhage and pseudo-membrane at places. There is extensive coagulation-necrosis with fibrinous exudation and abundance of polymorpho-nuclear leucocytes, and the structure of the mucous membrane, as well as that of the muscularis mucosa, is often lost in the exudation. Sometimes deep ulceration occurs, there is also great thickening of the submucosa, with infiltration of leucocytes, these being chiefly of the character of plasma cells. In the more chronic forms the changes correspond, but are more of a proliferative character. The mucous membrane is granular, and superficial areas are devoid of epithelium, whilst ulceration and pseudo-membrane are present in varying degree. In the stools the presence of a large number of degenerated polymorpho-nuclear leucocytes and

macrophages, with red corpuscles, points to bacillary rather than amœbic dysentery (Mackie). Another feature of bacillary dysentery is the fact that abscess of the liver does not occur as a complication.

Agglutination.—There is general agreement regarding the agglutination of this bacillus by the serum—that is, in the cases of dysentery from which the organism can be cultivated—and the reaction is of diagnostic value. The reaction may appear on the second day, and is most marked after from six to seven days in the acute cases. Agglutination of the Shiga bacillus in an hour in a serum dilution of one in fifty is usually accepted as being of diagnostic significance. The case of the Flexner bacillus is much more difficult; on the one hand, it is susceptible to agglutination by normal sera to such an extent that probably a positive result with dilutions more concentrated than 1–100 cannot be taken as indicating the presence of infection; on the other hand, the individuality of a strain used may be such that it is not agglutinated by sera originated by other strains. In chronic cases the reaction is less marked than in acute. It is difficult to make any general statements with regard to the effects of dysenteric sera on the different strains of the bacilli, but it may be said that generally a serum agglutinates the strain which produced it and the other strains of the same group in higher dilutions than it does the strains of the other group. It has been generally found that the serum from a case associated with strains of the Shiga-Kruse group has not agglutinated strains of the Flexner group, and corresponding results have been made in cases associated with the Flexner group. The sera of animals immunised with the bacilli are used for such tests, but great care must be exercised in their application, as the sera vary in different instances as regards their action on strains allied to that used for injection. As a rule, an anti-Y serum agglutinates strains of the Flexner group, but Martin and Williams found that one-sixth of the mannite-fermenting dysentery organisms cultivated by them were not agglutinated by a univalent-Y serum when first isolated, though half of these acquired this property on cultivation. It is doubtful whether a univalent serum can be got which will agglutinate all mannite-fermenting types. Agglutination of a dysentery bacillus has not been obtained with serum from cases other than those of dysentery, nor has a similar bacillus been cultivated from such sources. The reaction is also absent in those cases of dysentery which are purely amœbic in nature.

Pathogenic Properties.—The organism is pathogenic to guinea-

pigs and other laboratory animals, but, in these, characteristic changes in the intestine are often awanting. Shiga, however, obtained such effects by introducing the organism into the stomach of young cats and dogs, and confirmatory results were obtained by Flexner. Such attempts have been specially successful when the virulence of the organism has been previously exalted by intraperitoneal *passage*. In two cases, apparently well authenticated, a dysenteric condition has followed in the human subject from ingestion of pure cultures of the organism.

In the action of the bacillus a toxin may be concerned. If the organism be grown for two or three weeks in an alkaline bouillon, there appears in the culture medium, probably by autolysis of the bacteria, a toxin separable by filtration in the ordinary way. The optimum alkalinity is achieved by adding ·3 per cent. of soda to bouillon neutral to litmus, the resulting precipitate not being removed; free access of oxygen is permitted during growth. Apparently, the Shiga-Kruse strains yield the most toxic filtrates, and with the Flexner strain, the results of most observers show that soluble toxins cannot be obtained. The poison is very toxic to animals, especially rabbits, and however introduced into the body it causes after an incubation period hæmorrhagic enteritis with a diphtheritic-like exudate on the surface of the mucous membrane. Toxins isolated from different strains differ as regards the animals for which they are most toxic. The toxin is fairly resistant to heat, standing temperatures up to 70° C. without being injured.

It may be said that an aggressive reaction (*vide* p. 187) has also been described in the case of the dysentery bacillus.

Immunisation Experiments.—Both large and small animals have been immunised against the bacillus and also against its toxic filtrates. In the former case the immunisation has been commenced either with non-lethal doses of living cultures, or with cultures killed by heat. The nature of the immunisation is probably complex. When cultures have been used, a bactericidal serum, in which immune bodies and complements (*vide* Immunity) are concerned, is developed. When the toxin is used for immunisation, a serum protecting against the toxin is produced. According to some results, animals immunised with cultures are immune against the toxin, and *vice versa*. All races of animals do not lend themselves to immunisation.

Considerable work has been done in immunising large animals (horses, goats) against the soluble toxins of the dysentery bacillus with a view to obtaining therapeutic sera.

Doerr, using his toxin from the Shiga-Kruse strain, produced in horses an antitoxic serum having protective and curative properties in animals. This serum has been used in a number of cases of bacillary dysentery in man with good results. Shiga produced a polyvalent serum by injecting horses with agar cultures of different strains, and states that it has been used in Japan with good results in doses of 20–50 c.c. Further observation is necessary as to the therapeutic effects, in cases associated with the Flexner strain, of an antitoxin produced by the Shiga strain.

It will be seen that the evidence furnished is practically conclusive as to the causal relationship between this bacillus and one form of dysentery, a form, moreover, which is both widespread and embraces a large proportion of cases of the disease; and especially of importance is the fact that observations made independently in different countries have yielded practically identical results on this point.

Bacillus Dysenteriæ (*Ogata*).—Ogata obtained this bacillus in an extensive epidemic in Japan in which no amœbæ were present. He found in sections of the affected tissues enormous numbers of small bacilli of about the same thickness as the tubercle bacillus, but very much shorter. These bacilli were sometimes found in a practically pure condition. They were actively motile, and could be stained by Gram's method. He also obtained pure cultures from various cases and tested their pathogenic effects. They grew well on gelatin, at the ordinary temperature producing liquefaction, the growth somewhat resembling that of the cholera spirillum. By injection into cats and guinea-pigs, as well as by feeding them, this organism was found to have distinct pathogenic effects; these were chiefly confined to the large intestine, hæmorrhagic inflammation and ulceration being produced. It still remains to be determined whether this organism has a causal relationship to one variety of dysentery.

Summer Diarrhœa.

As has been already stated, the bacillus of dysentery, the b. coli, and the b. enteritidis sporogenes have been found associated with epidemics of this disease. This indicates that the condition may be originated by a variety of organisms, and it is further probable that the clinical features in different epidemics vary. This is to a certain extent illustrated by the condition of the stools. In Britain these are usually green, watery, slimy, and putrid, without blood or mucus, but in many outbreaks in America blood and mucus are present. The multiple origin of the disease has been illustrated by the work of Morgan, who, in a careful investigation of the disease in Britain,

has been unable to find evidence of the dysentery bacillus being present. He has, however, very frequently (in 63 per cent. of the cases examined) found in the stools and intestine a bacillus ("Morgan's No. 1 bacillus") which is a motile Gram-negative organism producing acid and slight gas formation in glucose, lævulose, and galactose, and no change in lactose, mannite, dulcite, maltose, dextrin, cane-sugar, inulin, amygdalin, salicin, arabinose, raffinose, sorbite, or erythrite; it further causes indol formation, and in litmus milk slowly originates an alkaline reaction. It produces diarrhœa and death in young rabbits, rats, and monkeys when these animals are fed on cultures. It is thus possible that in this bacillus we have still another cause of the disease. Morgan has found that in diarrhœa cases the lactose fermenters, so characteristic of normal fæces, are relatively less numerous and tend to be replaced by non-fermenters of lactose. His bacillus has been found in a certain proportion of normal children, but this especially during the epidemic season; it has also been found in flies.

Isolation and Differentiation of Coli-Typhoid Bacilli by Culture.

The existence of a large group of intestinal diseases with similar clinical features caused by closely allied bacteria makes the differentiation of these affections and of the causal bacteria a difficult problem. The difficulty is increased where, as in recent war conditions, several of these diseases may be simultaneously prevalent, each on a considerable scale. The best solution of the bacteriological problem is found in the isolation of the organisms from the stools or blood of the patient, but here often the best methods may fail to yield cultures, especially when, as has often been the case, the individual does not come under observation till the acute phase of the disease has passed. Moreover, cases occur where more than one member of the pathogenic intestinal bacteria may be present. The isolation method should, however, invariably be attempted.

Post mortem, organisms may be isolated from the solid organs, especially from the spleen, from the mesenteric glands, from the heart-blood, especially in typhoid, paratyphoid, and Gaertner infections—to a much less extent in dysentery. The intestine, of course, may also be a source of culture.

During life the bacilli may be obtained in culture in the following ways:—

(*a*) *From the Stools.*—One or two loopfuls of fæces are emulsified in 10 c.c. bouillon until the medium just begins to be slightly opaque and the tube is allowed to stand until any solid particles have subsided. A loopful from the upper part of the fluid is placed on one or more MacConkey lactose agar plates (or on one of the other similar media) and well spread—the plate being incubated with the medium uppermost. Browning's brilliant-green method (p. 51) may also be recommended. In any case the presence on MacConkey plates of colourless colonies of Gram-negative bacilli constitutes presumptive evidence of the existence of pathogenic members of the coli-typhoid group in the fæces. Some of these colonies should now be picked off into bouillon and into mannite tubes. The former are used after a few hours' incubation for investigating motility—the latter for observing fermentation. Growth in mannite without acid or gas points to the presence of the b. dysenteriæ, Shiga, if the organism is non-motile, or of Morgan's No. 1 bacillus, if motile; the development of acid without gas may be due to the b. typhosus, if the bacillus be motile, or to the b. dysenteriæ (Flexner or Y) if non-motile; a culture showing acid and gas associated with motility in the organism indicates one of the para-typhoid bacilli or the b. Gaertner.[1] Agglutination observations may now be made (see *infra*) and a set of culture tubes appropriate to the organism suspected to be present may be put up; it is well to include amongst these a gelatine tube, to exclude non-pathogenic varieties, and one of lactose—the latter to be kept under observation for several weeks in case the bacillus be a slow lactose fermenting b. coli. In this connection the fact must always be borne in mind, in dealing with any coli-typhoid bacillus, that its fermentative capacities may be very slowly manifested.

In any extensive investigation of intestinal infections atypical bacilli will from time to time be encountered which show aberration in the presence or absence of motility, in the formation of indol, in unusual fermentative reactions, etc.; the significance of these may be difficult to determine.

The fæces always constitutes an important source of cultures in the diseases under consideration. In typhoid and paratyphoid fevers the causal bacteria may be detected during the incubation period and during the febrile stage, though towards the end of the acute illness the numbers may diminish, and if ulceration is not a marked feature their numbers may not be great at any time. They may persist during convalescence, but gradually disappear in the course of from a few weeks to three months, except in carrier cases. Similar facts obtain in bacillary dysentery.

(*b*) *From the Blood.*—The bacilli of the group may be isolated from the blood by ordinary methods (see p. 70), but a special method is often also used. In this, 5 c.c. of the blood are placed in 10 c.c. sterilised ox bile; the mixture is incubated for from one to seven days, and from time to time the presence of non-lactose fermenters is tested by inoculating MacConkey plates. In typhoid and paratyphoid infections the organisms have been stated to have been isolated from the blood during the pre-febrile stage and are very usually present while fever exists, especially when the b. paratyphosus is the active agent. In bacillary dysentery a blood infection is not common. It may be said generally that the isolation of an organism of the group from the blood during an acute illness probably furnishes the most significant evidence as to its being the cause of the condition present.

---

[1] For fuller details consult Henderson Smith, *Brit. Med. Journ.*, 1915, vol. ii. p. 1; Ledingham and Penfold, *ibid. idem.*, p. 704.

(*c*) *From the Urine.*—In typhoid fever the bacilli are present in at least 25 per cent. of cases, especially late in the disease, probably chiefly where there are groups of the organism in the kidney substance. The organism can also be found in paratyphoid infections. For methods of examining the urine, see pp. 50, 73. As has been stated, the b. coli is a frequent cause of suppurations about the genito-urinary tract, and thus often appears in the urine. The significance of its presence is greatest when accompanied by cytological evidence of the co-existence of inflammatory conditions.

The ultimate differentiation of the pathogenic varieties of the coli-typhoid groups is effected by the study of their agglutination reactions to stock sera prepared by means of typical cultures (see below, p. 393). During the war, high-titre sera agglutinating the various bacilli in 1 : 5000, or even higher, dilution, have come into general use for differentiating organisms when isolated, the sedimentation method being most convenient when dealing with numerous organisms.

The Agglutination Reactions of the Coli-Typhoid Bacilli and Their Relation to the Differentiation of Strains.

We have seen that all the members of the group produce agglutinating sera during the infections they originate. The specificity of the reaction in each case is sufficient to constitute a basis on which a diagnosis of the condition originated may be rested. It proceeds from the action of the infecting organism; thus a strain actually isolated from a patient frequently is agglutinated by his serum. The reaction is in practice, however, usually elicited by the use of strains isolated from previous cases.

Technique.—There are a number of general points which here require attention. All finer work on agglutination must be carried out by means which ensure accurate measurement of the dilutions prepared, and further a sedimentation method—interpreted either by naked-eye or low-power microscopic examination—ought to be employed. We have already, in dealing with the Widal reaction in typhoid fever, detailed some of the precautions to be observed in obtaining the necessary cultures. In the case of the b. typhosus it is easy from small, localised, clinically typical outbreaks of the disease to isolate undoubted strains of the organism and to select those which readily undergo agglutination. Most laboratories are provided with such cultures which have been proved to be trustworthy by years of trial. The situation is different with the other pathogenic members of the group, especially when, as under war condition, several different intestinal diseases are prevalent at the same time. Under such circumstances a number of strains may be obtained which differ in their capacities for being agglutinated—a preliminary difficulty being that organisms freshly isolated off such media as MacConkey's agar often must be subcultured daily on plain agar for some time before they

manifest agglutinability at all. Thus the only criteria for preferring a strain are that it is agglutinated by more sera than the other strains available or that it is a sub-culture of what may be termed a historic strain. Even with the most carefully selected strain, however, a serum which agglutinates it may have no effect on an organism which, according to the other available evidence, ought to be identified as belonging to the species to which the selected strain belongs. These remarks apply with special cogency to the paratyphoid bacilli and to Flexner's dysentery bacillus—strains of both of which types appear to possess much greater individuality than is the case with the typhoid bacillus on the one hand or with Shiga's dysentery bacillus on the other. Given a typical strain, it is to be noted that successive cultures may show differences in agglutinability. Thus the culture media used should be as uniform as possible in composition. The best medium for growing cultures for agglutination tests is probably a pale veal bouillon which has not been too long autoclaved, and it is well to make daily cultures for from four to six weeks on this medium. After such preparation a 24 to 48 hours' culture may be used as the emulsion for agglutination observations, though many observers prefer to use agar slope cultures washed off with saline or bouillon. Though living bacilli may be more readily agglutinated than dead organisms there is great convenience in using killed cultures as recommended by Dreyer (p. 118), greater uniformity being thereby attained. It is of great importance for routine work and especially when successive observations on the same case are to be made that the emulsions used should contain approximately the same number of bacilli per unit of volume. Ledingham recommends an emulsion of about 2000 million bacilli per c.c. ; if the degree of opacity of such a concentration be observed, successive emulsions can be readily standardised. It is here that killed cultures are specially convenient, as large batches of these can be easily prepared. With regard to the time and temperature factors in an agglutination reaction, when relatively high concentrations of serum are being used, a full effect may be obtained in from ½–1 hour at room temperature especially with the microscopic method ; with low concentrations (here it is advisable to practise the sedimentation technique) the mixtures should be kept in a water bath for two hours at 55° C.

The diagnosis of the nature of an intestinal infection by the agglutination method is relatively simple if the serum agglutinates only one species of bacterium. The chief point to be borne in mind here is that sometimes the serum of a normal individual may agglutinate an organism. Such a phenomenon, however, is usually only met with when the serum is in strong concentration, and the difficulty can be overcome by employing dilute solutions. Thus in suspected typhoid fever if the patient's serum in a dilution of 1–30 of bouillon or normal saline agglutinates the typhoid bacillus a positive diagnosis may be given. In paratyphoid A infections a diagnosis may be founded on agglutination with a dilution of 1–10, in paratyphoid B infections with a dilution of 1–25, and in Shiga dysentery infections with a dilution of 1–50. In the case of Flexner's dysentery bacillus agglutination may occur with normal serum

in such a high dilution as to make the differentiation of such a reaction from one indicative of infection difficult. A positive diagnosis cannot be founded on an agglutination with a concentration of serum higher than 1–100; some observers, in fact, would demand a result with a still lower concentration before diagnosing the presence of this variety of dysentery.

The chief difficulty in interpreting observations of agglutination reactions is met with when in infected or inoculated individuals the serum agglutinates more than one member of the group. From this point of view the pathogenic members of the coli-typhoid group fall into two sub-groups, one of which contains the typhoid bacillus, the paratyphoid bacilli, and the bacillus of Gaertner, and the other, the two types of dysentery bacilli; a serum which frankly agglutinates a member of one sub-group usually has little or no effect on the members of the other sub-group. The occurrence of such cross-agglutination is attributed to the fact that the causal organism in an infection not only stimulates the production of agglutinins towards itself (primary or homologous agglutinins), but also of agglutinins acting on kindred species (secondary or heterologous agglutinins). The primary agglutinins are usually formed in greater amount than the secondary, and thus the organism which is agglutinated in the highest dilution may usually be looked on as the causal bacterium. A serum may, however, contain primary agglutinins to more than one organism. This may arise where more than one infection exists at the same time in one individual, or where primary agglutinins originating from a previous infection persist in the body, or—what is at present the most frequent source of confusion—where such persistence is the relic of a previous preventive inoculation. In order to surmount the difficulties arising from such complications some observers have used the method of making frequent—it may be daily—estimations during an illness of the highest dilutions in which the serum will agglutinate each of the organisms which may be suspected to be the causal agent. This method has been specially elaborated by Dreyer, Ainley Walker, and Gibson, who hold that the study of the curves of the agglutinin content of the serum gives valuable information. Thus, a regular and marked rise in the curve of one of the typhoid-paratyphoid sub-group, to a maximum between the 16th and 24th day (especially between the 18th and 20th), with a gradual fall thereafter indicates an infection with that bacillus; if in such a case primary agglutinins are present towards other members of the sub-group (due, it may be, to a previous vaccination), the curves

of these residuary agglutinins either show no change or a slight rise with a fall to their initial levels, or a marked rise, synchronous or slightly earlier than that of the curve of the infecting organism: the confusion introduced by the last occurrence may be dispelled by the fact that the initial content of the serum in inoculation agglutinins may be higher than that in infection agglutinins. The explanation of the state of the inoculation curves is that after, say, antityphoid inoculation, the curve against the b. typhosus rises rapidly to a maximum just as during infection, but falls very slowly over a period of, it may be, many months. It is an interesting fact that an acute paratyphoid B infection seems to have the effect of stimulating a fresh formation of primary agglutinins against the b. typhosus if these be already present in the serum.

In trying to differentiate between primary and secondary agglutinins the absorption method (p. 119) may also be used. Castellani studied this method in experimental infections of rabbits. He found that, when an animal had been immunised with the b. typhosus, this organism would *in vitro* remove from the serum not only the primary typhoid agglutinins but also the secondary agglutinins, which might act on, say, the b. coli. If, however, the animal had been immunised with both the b. typhosus and the b. coli, then the b. typhosus could not absorb from the serum the (primary) b. coli agglutinins. Castellani therefore put forward the view that by this means primary could be differentiated from secondary agglutinins, and consequently pure could be distinguished from mixed infections. The method has been applied in natural human infections and may provide data of value especially when these are correlated with the results of the other methods described.

From what has been said it will be readily gathered that agglutination reactions are of great value in the diagnosis of intestinal infections and may enable a positive opinion to be given in cases where attempts to isolate the causal organism by culture fail. This is especially true of infections which have reached a chronic stage in which cultures are often unsuccessful in, it may be, 50 per cent. of the cases investigated.

Differentiation of Unknown Bacilli through Agglutination Reactions.—If the relation of a bacillus to its anti-serum is specific it is obvious that the properties of such a serum can be utilised for the recognition of bacilli of unknown species. Thus if a serum originated by the b. typhosus agglutinates a bacillus with the cultural characters of this organism the unknown strain is almost certainly the typhoid bacillus; this is especially likely

to be the case if the two organisms are clumped by approximately the same dilution of the serum. On this principle is now based the ultimate determination of the species to which a strain isolated by culture belongs. It is usually applied immediately after the organism has been classified into its cultural group by its behaviour towards mannite and by the presence or absence of motility (see p. 389). In the use of the test, high-titre sera obtained by the immunisation of animals with historic or otherwise reliable strains are employed. The observer must be provided with sera against the b. typhosus, b. paratyphosus A, b. paratyphosus B, b. gaertner, b. dysenteriæ, Shiga, and b. dysenteriæ Y (the latter is used as it agglutinates a large number of Flexner strains which, on account of their dominant individuality, do not readily yield cross-agglutinins towards each other); the titre of each serum to the strain which produced it must be known. In the diagnosis of bacterial strains the sedimentation method should be employed.

In any extended investigation of intestinal infections bacilli will be met with not agglutinable by any sera which on the cultural data seem to be appropriate to them, and yet the conditions of their isolation may point to their etiological connection with the disease with which they are associated. This phenomenon is at present unexplained.

Varieties of B. Coli.

From work done not only with bacteria isolated from pathological conditions, but in connection with the bacteriology of water, milk, and fæces, it has been found that an enormous number of organisms exists which have the capacity of fermenting glucose and lactose, but which, when further investigated, present individual differences. Much has been done in attempting to differentiate these so-called "lactose fermenters" from one another. Here the work of MacConkey may be taken as constituting one of the best attempts at such further classification, and it has the merit of simplifying a technique unduly complicated by the use of fermentation tests in a great series of sugars, on which the various sub-groups have all the same effect. MacConkey is of opinion that certain of the tests applied to the lactose fermenters in reality give little information. These are, first, the growth on litmus whey, observation of which only corroborates what is observed with litmus milk; second, observation of fluorescence on neutral-red lactose media (on account of the inconstancy of the occurrence of this change in lactose fermenters, and from the fact that many other bacteria also produce it); third, the reduction of nitrates—this appears to be a common property of nearly all the members of the group; fourth, observation of differences in the naked-eye or low-power appearances on gelatin; these are very inconstant, and different colonies of the same organism may show different appearances. On the other hand, important information may be obtained by the observation of the Voges and Proskauer reaction (p. 356).

With regard to sugars, MacConkey concludes that in the differentiation of the lactose fermenters, the only sugars necessary are lactose, saccharose, dulcite, adonite, inulin, inosite, and mannite. Using these, a preliminary classification can be made from the actions on cane-sugar and dulcite, and four groups are constituted: I. Organisms not affecting either cane-sugar or dulcite. II. Organisms having no action on cane-sugar, but fermenting dulcite. III. Organisms fermenting both cane-sugar and dulcite. IV. Organisms fermenting cane-sugar, but having no action on dulcite. Of the first, the bacillus acidi lactici of Hüppe may be taken as a type; of the second, the bacillus coli communis of Escherich; of the third, bacillus Friedländer; of the fourth, the bacillus lactis aerogenes and the bacillus cloacæ. Group IV. is further subdivided into sub-group 1, in which there is no liquefaction of gelatin and an absence of the Voges and Proskauer reaction; 2, with no liquefaction of gelatin, presence of Voges and Proskauer's reaction (bacillus lactis aerogenes); 3, with liquefaction of gelatin, presence of Voges and Proskauer's reaction (bacillus cloacæ); 4, with liquefaction of gelatin and production of a yellow pigment. Taking the properties named as type characteristics, the great mass of lactose fermenters can be further differentiated by the application of the other sugar tests. It is well to refer any organism found as belonging to one or other of the types, as in most cases no name has been assigned. Examples are constantly met with in work on water or fæcal contents.

Although many of the named varieties were originally described in connection with other bacterial processes, all these bacteria are of frequent occurrence, especially in the human and animal intestine. As in the case of the members of the food-poisoning group, great difficulty has been experienced in identifying the types from mere description, and considerable complication has arisen from the fact that before the elaboration of the modern differentiation technique, different observers identified organisms as belonging to a classical type, which have now been found not to conform in properties with the historic strains; here again, it is now customary during classification work to have at hand such historic strains in order that comparative parallel observations may be made.

With regard to the type strains, a few words may be added. The original bacillus coli communis of Escherich was isolated from the intestine of newly-born infants in connection with the first appearance of bacteria in the alimentary tract. About the same time, an organism now known as the bacillus neapolitanus was obtained by Emmerich in an outbreak of choleraic disease in Naples, and this organism was looked upon as identical with Escherich's bacillus, but it ferments saccharose, on which Escherich's has no effect. The bacillus acidi lactici of Hüppe was stated by this observer to be the chief cause of the souring of milk. It is now known that a large number of organisms of the same type, but differing slightly in cultural characters, are concerned in this process, and, as a matter of fact, MacConkey found the presence of the classical strain to be relatively infrequent in milk. The bacillus lactis aerogenes was originally described by Escherich, in connection with his work on the bacteriology of the intestine in children, as an organism differing from the ordinary milk-souring bacteria by its producing gas from milk in the absence of air. Although it is a free gas-producer, this property is not specific for it, and within recent years it has attracted attention chiefly from its apparently being closely allied to the bacillus pneumoniæ of Friedländer. Like the latter, this organism is stated when injected into animals to appear in a capsulated form. Another member of this

group is bacillus oxytocus perniciosus, which is said originally to have been isolated from milk. This organism, along with the bacillus vesiculosus and an organism denominated No. 71, were found by MacConkey to be of very common occurrence in human and animal fæces.

In work of the kind with which we are dealing, two other organisms are not infrequently observed which morphologically belong to the colityphoid group, but neither of which is a lactose fermenter. These are the bacillus fæcalis alcaligenes, and the bacillus coli anaerogenes. The reactions of these will be found in the Table on p. 396. The latter bacillus somewhat resembles the typhoid bacillus, but produces acid in lactose and can be distinguished by agglutinating reactions.

When any question arises regarding the relationships of an organism isolated under saphrophytic conditions and resembling some definite pathogenic type, important information can often be obtained by studying its agglutinating reactions. In such a case the effect of sera produced by the pathogenic type upon the unknown organism, and of sera produced by injection into animals of the pathogenic type in question, ought to be studied.

The Question of Mutation.—It is becoming more and more recognised as our knowledge of pathogenic bacteria advances that around each particular type form we must group a number of variants which closely resemble it. This is specially true of some of the members of the colityphoid group; here the introduction of a variety of media makes the recognition of variants comparatively easy. Thus, to take the b. dysenteriæ, not only have different epidemics yielded different strains, but what is somewhat perplexing, similar differences, even in the fundamental character of behaviour towards mannite, have been observed in strains isolated from different cases during the same epidemic. Such facts might even raise doubts as to the etiological relationship of the organism to the disease, and certainly make it necessary to consider whether the conditions of growth existing in the animal body are capable of accounting for the variations observed.

Several facts bearing upon the question are now known. Neisser from a non-lactose fermenter under his observation found a new strain capable of fermenting lactose appear in his cultures. Of greater importance, however, is the origination of such mutations under experimental conditions. Thus, Twort found that by prolonged sub-culturing on a lactose-containing medium the typhoid bacillus developed the capacity of forming acid from this sugar, and Penfold has shown that this organism can similarly produce acid from dulcite. Penfold has also observed that the capacity of the b. coli to produce gas from various sugars can be modified and in certain cases suppressed by a previous growth on a medium containing monochloracetic acid. Similar results have been obtained with other organisms, and the important fact has been elicited that the changes in capacity are related to the chemical constitution of the sugars employed, as for instance when the variant, while unable to produce gas from certain pentoses, can to a certain extent originate the change in hexoses. The isolation of variants is frequently made possible by alterations in the naked-eye appearances of surface colonies and the development upon them of papillæ, the bacteria in these excrescences being found to present different properties from those in the flat part of the colony. The investigation of these mutations is not only of great scientific importance, but may throw light on the multiplicity of strains which has been observed under natural conditions.

CHAPTER XVI.

DIPHTHERIA.

THERE is no better example of the valuable contributions of bacteriology to scientific medicine than that afforded in the case of diphtheria. Not only has research supplied a means of distinguishing true diphtheria from conditions which resemble it, but the study of the toxins of the bacillus has explained the manner by which the pathological changes and characteristic symptoms of the disease are brought about, and has led to the discovery of the most efficient means of treatment, namely, the anti-diphtheritic serum.

Historical.—The first account of the bacillus now known to be the cause of diphtheria was given by Klebs in 1883, who described its characters in the false membrane, but made no cultivations. It was first cultivated by Löffler from a number of cases of diphtheria, his observations being published in 1884, and to him we owe the first account of its characters in cultures and some of its pathogenic effects on animals. The organism is for these reasons known as the Klebs-Löffler bacillus, or simply as Löffler's bacillus. By experimental inoculation with the cultures obtained, Löffler was able to produce false membrane on damaged mucous surfaces, but he hesitated to conclude definitely that this organism was the cause of the disease, for he did not find it in all the cases of diphtheria examined, he was not able to produce paralytic phenomena in animals by its injection, and, further, he obtained the same organism from the throat of a healthy child. This organism became the subject of much inquiry, but its relationship to the disease may be said to have been definitely established by the brilliant researches of Roux and Yersin, which showed that the most important features of the disease could be produced by means of the separated toxins of the organism. Their experiments were published in 1888–90.

General Facts.—Without giving a description of the pathological changes in diphtheria, it will be well to mention the outstanding features which ought to be considered in connection with its bacteriology. In addition to the formation of false membrane, which may prove fatal by mechanical effects, the chief clinical phenomena are the symptoms of general poisoning,

great muscular weakness, tendency to syncope, and albuminuria; also the striking paralyses which occur later in the disease, and which may affect the muscles of the pharynx, larynx, and eye, or less frequently the lower limbs (being sometimes of paraplegic type), all these being grouped together under the term "post-diphtheritic paralyses." It may be stated here that all these conditions have been experimentally reproduced by the action of the bacillus of diphtheria, or by its toxins. Other bacteria are, however, concerned in producing various secondary inflammatory complications in the region of the throat, such as ulceration, gangrenous change, and suppuration, which may be accompanied by symptoms of general septic poisoning. The detection of the bacillus of Löffler in the false membrane or secretions of the mouth is to be regarded as supplying the only certain means of diagnosis of diphtheria.

Bacillus Diphtheriæ.—*Microscopical Characters.*—If a film preparation be made from a piece of diphtheria membrane (in the manner described below) and stained with methylene-blue, the bacilli are found to have the following characters: They are slender rods, straight or slightly curved, and usually about 3 μ in length, their thickness being a little greater than that of the tubercle bacillus. The size, however, varies somewhat in different cases, and for this reason varieties have been distinguished as small and large, and even of intermediate size. It is sufficient to mention here that in some cases most are about 3 μ in length, whilst in others they may measure fully 5 μ. Corresponding differences in size are found in cultures. They stain deeply with the blue, sometimes being uniformly coloured, but often showing, in their substance, little granules more darkly stained, so that a dotted or beaded appearance is presented. Sometimes the ends are swollen and more darkly stained than the rest; often, however, they are rather tapered off (Fig. 110). In some cases the terminal swelling is very marked, so as to amount to clubbing, and with some specimens of methylene-blue these swellings and granules stain of a violet tint. Both the granules and clubbing, however, are less frequent than in cultures. There is a want of uniformity in the appearance of the bacilli when compared side by side. They usually lie irregularly scattered or in clusters, the individual bacilli being disposed in all directions. Some may be contained within leucocytes. They do not form chains, but occasionally forms longer than those mentioned may be found, and these specially occur in the spaces between the fibrin as seen in sections.

Distribution of the Bacillus.—The diphtheria bacillus may

be found in the membrane wherever it is formed, and may also occur in the secretions of the pharynx and larynx in the disease. It may be mentioned that distinctions formerly drawn between true diphtheria and non-diphtheritic conditions from the appearance and site of the membrane, have no scientific value, the only true criterion being the presence of the diphtheria bacillus. The occurrence of a membranous formation produced by streptococci

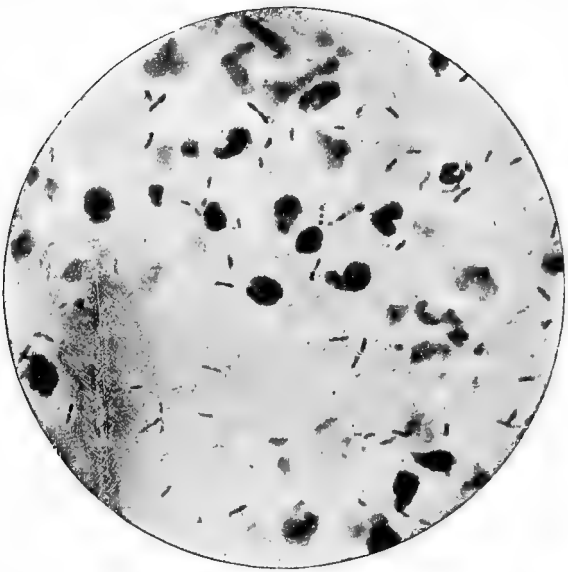

FIG. 110.—Film preparation from diphtheria membrane, showing numerous diphtheria bacilli. One or two degenerated forms are seen near the centre of the field. (Cultures made from the same piece of membrane showed the organism to be present in practically pure condition.)

Stained with methylene-blue. ×1000.

has already been mentioned (p. 211). Virulent diphtheria bacilli have been found in a considerable proportion of cases of fibrinous rhinitis. In the case of any nasal lesion, however, the test for virulence should always be made, as diphtheria-like bacilli without virulence are of comparatively common occurrence.

In diphtheria the membrane has a somewhat different structure, according as it is formed on the surface covered with stratified squamous epithelium, as in the pharynx, or on a surface covered by ciliated

epithelium, as in the trachea. In the former situation necrosis of the epithelium occurs either uniformly or in patches, and along with this there is marked inflammatory reaction in the connective tissue beneath, attended by abundant fibrinous exudation. The necrosed epithelium becomes raised up by the fibrin, and its interstices are also filled by it. The fibrinous exudation also occurs around the vessels in the tissue beneath, and in this way the membrane is firmly adherent. In the trachea, on the other hand, the epithelial cells rapidly become shed, and

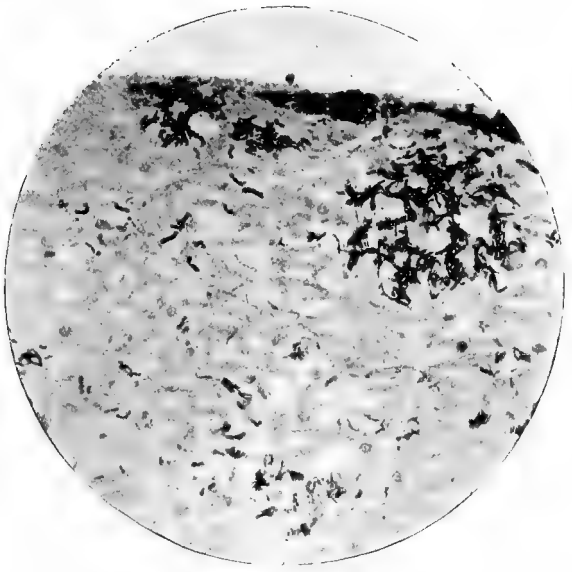

FIG. 111.—Section through a diphtheritic membrane in trachea, showing diphtheria bacilli (stained darkly) in clumps, and also scattered amongst the fibrin. Some streptococci are also shown towards the surface on the left side.
Stained by Gram's method and Bismarck-brown. ×1000.

the membrane is found to consist almost exclusively of fibrin with leucocytes, the former arranged in a reticulated or somewhat laminated manner, and varying in density in different parts. The membrane lies upon the basement membrane, and is comparatively loosely attached.

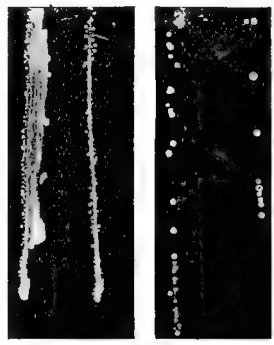
The position of the diphtheria bacilli varies somewhat in different cases, but they are most frequently found lying in oval or irregular clumps in the spaces between the fibrin, towards the superficial, that is, usually, the oldest part of the false membrane (Fig. 111). There they may be in a practically pure condition,

though streptococci and occasionally some other organisms may be present along with them. They may occur also in deeper parts, but are rarely found in the fibrin around the blood vessels. On the surface of the membrane they may be also seen lying in large numbers, but are there accompanied by numerous other organisms. Occasionally a few bacilli have been detected in the lymphatic glands. As Löffler first described, they may be found after death in pneumonic patches in the lung, these being due to a secondary extension by the air passages. They have also been occasionally found in the spleen, liver, and other organs after death. This occurrence is probably to be explained by an entrance into the blood stream shortly before death. The diphtheria bacillus may also infect other mucous membranes. It is found in true diphtheria of the conjunctiva, and may also occur in similar affections of the vulva and vagina; some of these cases have been treated successfully with diphtheria antitoxin.

Association with other Organisms.—The diphtheria organism is sometimes present alone in the membrane, but more frequently is associated with some of the pyogenic organisms, the streptococcus pyogenes being the commonest. The staphylococci, and occasionally the pneumococcus or the bacillus coli, may be present in some cases. Streptococci are often found lying side by side with the diphtheria bacilli in the membrane, and also penetrating more deeply into the tissues. In some cases of tracheal diphtheria we have found streptococci alone at a lower level in the trachea than the diphtheria bacilli, where the membrane was thinner and softer, the appearance in these cases being as if the streptococci acted as exciters of inflammation and prepared the way for the bacilli. It is still a matter of dispute as to whether the association of the diphtheria bacillus with the pyogenic organisms is a favourable sign or the contrary, though on experimental grounds the latter is the more probable. We know, however, that some of the complications of diphtheria may be due to the action of pyogenic organisms. The extensive swelling of the tissues of the neck, sometimes attended by suppuration in the glands, and also various hæmorrhagic conditions, have been found to be associated with their presence; in fact, in some cases the diphtheritic lesion enables them to get a foothold in the tissues, where they exert their usual action and may lead to extensive suppurative change, to septic poisoning or to septicæmia. In cases where a gangrenous process is superadded, a great variety of organisms may be present, some of them being anaerobic. Against such complications produced

by other organisms anti-diphtheritic serum produces no favourable effect.

Cultivation. — The diphtheria bacillus grows best in cultures at the temperature of the body; growth still takes place at 22° C., but ceases about 20° C. The best media are the following: Löffler's original medium (p. 42), solidified blood serum, alkaline blood serum (Lorrain Smith), blood agar, and the ordinary agar media. If inoculations be made on the surface of blood serum with a piece of diphtheria membrane, colonies of the bacillus may appear in twelve hours, and are well formed within twenty-four hours, often before any other growths are visible. The colonies are small circular discs of opaque whitish colour, their centre being thicker and of darker greyish appearance, when viewed by transmitted light, than the periphery. Their margins are at first regular, but later they become wavy or even crenated. On the second or third day they may reach 3 mm. in size, but when numerous they remain smaller. On the agar media the colonies have much the same appearance (Fig. 112) but grow less quickly, and sometimes they may be comparatively minute, so as rather to resemble those of the streptococcus pyogenes. In stroke cultures the growth forms a continuous layer of the same dull whitish colour, the margins of which often show single colonies partly or completely separated. On *gelatin*



a *b*

FIG. 112. — Cultures of the diphtheria bacillus on an agar plate; twenty-six hours' growth. (Natural size.)

FIG. 113.—Diphtheria colonies, two days old, on agar. ×8.

at 22° C. a puncture culture shows a line of dots along the needle track, whilst at the surface a small disc forms, rather thicker in the middle. In none of the media does any liquefaction occur. In *bouillon* the organism produces a turbidity which soon settles to the bottom and forms a powdery layer on the wall of the vessel. If the growth is started on the surface and the flask is kept at rest, a distinct scum forms, and this is especially suitable for the development of toxin. Ordinary bouillon becomes acid during the first two or three days, and several days later again acquires an alkaline reaction. If, however, the bouillon is dextrose-free (p. 79) the acid reaction does not occur.

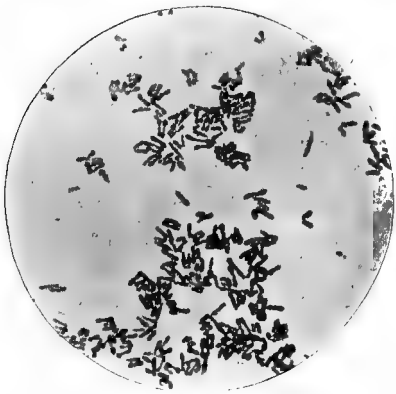

FIG. 114.—Diphtheria bacilli from a twenty-four hours' culture on agar. Stained with methylene-blue. ×1000.

It would be a great advantage if virulent diphtheria bacilli could always be distinguished by their growth characters and fermentation reactions, but unfortunately this is not the case. According to Graham-Smith the diphtheria bacillus ferments not only glucose, but also galactose, lævulose, maltose, dextrin, and usually also glycerin and lactose in older cultures; mannite and saccharose are not fermented. Of these reactions Hine considers that fermentation of glucose and dextrin and non-fermentation of saccharose indicate a true diphtheria bacillus. But, on the one hand, avirulent organisms may conform with these reactions

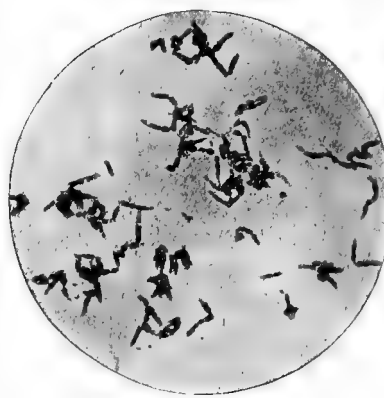

FIG. 115.—Diphtheria bacilli of larger size than in previous figure, showing also irregular staining of protoplasm. From a three days' agar culture. Stained with weak carbol-fuchsin. ×1000.

(J. F. Smith), and, on the other hand, virulent organisms may not conform. It is accordingly not possible to substitute fermentation reactions for the virulence test.

In culture media the bacilli show the same characters as in the membrane, but the beading is a more marked feature, except in the very youngest cultures, and sometimes the stained protoplasm has a sort of septate appearance (Figs. 114, 115). Some varieties stain fairly uniformly with methylene-blue, but show granules when stained by Neisser's method. They are at first fairly uniform in size and shape, but later involution forms may appear, especially on the less favourable media, such as agar. Many are swollen at their ends into club-shaped masses which stain deeply, and the protoplasm becomes broken up into globules with unstained parts between (Fig. 116). Some become thicker throughout, and segmented so as to appear like large cocci, and others show globules at their ends, the rest of the rod appearing as a faintly stained line. Occasionally branched forms are met with. The bacilli are non-motile, and do not form spores.

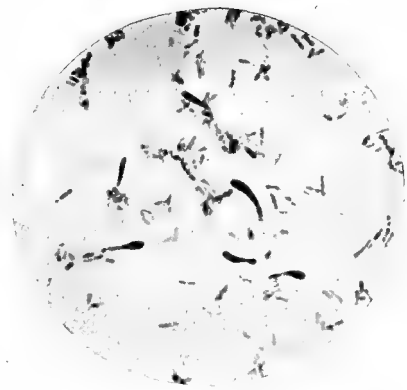

FIG. 116.—Involution forms of the diphtheria bacillus; from an agar culture of seven days' growth. See also Plate III., Fig. 13. Stained with carbol-thionin-blue. ×1000.

Staining. — They take up the basic aniline dyes, *e.g.*, methylene-blue in watery solution, with great readiness, and stain deeply, the granules often giving the metachromatic reaction as described. They are Gram-positive, though they are rather more easily decolorised than the pyogenic cocci. By Neisser's stain (p. 114) the bacilli are seen to contain granules stained almost black, the rest of the bacillary substance being yellowish-brown, or by the erythrosin method, pink (Plate III., Fig. 12). In applying the stain a serum culture of 18–24 hours' growth ought to be used. The granules brought out by Neisser's method are often not visible in a methylene-blue preparation.

Neisser's stain is undoubtedly an important auxiliary in the recognition of the diphtheria bacillus, but the results of its use are to be interpreted

with caution. Granules staining black are not peculiar to the diphtheria bacillus. Some cocci, often giving a metachromatic reaction with methylene-blue, may be stained black; and other bacilli may contain such granules. A not uncommon organism with such a character occurring in the throat is a strepo-bacillus with square ends; it has no resemblance to the diphtheria bacillus in a methylene-blue preparation, but when stained by the Neisser method may give an appearance very like that organism. On the other hand, a culture of Hofmann's pseudo-diphtheria bacillus (p. 415) reacts negatively with Neisser's stain: at most a few scattered granules may occur in the preparation, but the bacilli have not the beaded appearance. It will be found a good working plan to use the Neisser stain only after finding bacilli in a film from a serum culture stained by methylene-blue, which present the features of the diphtheria bacillus. Such bacilli should react positively to the Neisser stain before being accepted as such. The stain is of special service in the case of the smaller forms of the diphtheria bacillus, the details of whose structure are imperfectly differentiated by methylene-blue. And again when the diphtheria bacilli are scanty they may be overlooked in a methylene-blue preparation, whereas they are more readily detected in a Neisser preparation.

All true diphtheria give the characteristic appearance with the Neisser stain, but it is of importance to observe that some hard waters interfere with the reaction. In such circumstances distilled water ought always to be used for washing the preparations.

Powers of Resistance, etc.—In cultures the bacilli possess long duration of life; at room temperature they may survive for two months or longer. In the moist condition, whether in cultures or in membranes, they have a low power of resistance, being killed at 60° C. in a few minutes. On the other hand, in the dry condition they have great powers of endurance. In membrane which is perfectly dry, for example, they can resist a temperature of 98° C. for an hour. Dried diphtheria membrane, kept in the absence of light and at the room temperature, has been proved to contain diphtheria bacilli still living and virulent at the end of several months. The presence of light, moisture, or a higher temperature, causes them to die out more rapidly. Corresponding results have been obtained with bacilli obtained from cultures and kept on dried threads. These facts, especially with regard to drying, are of importance, as they show that the contagion of diphtheria may be preserved for a long time in the dried condition.

Effects of Inoculation.—In considering the effects produced in animals by experimental inoculations of pure cultures, we have to keep in view the local changes which occur in diphtheria, and also the symptoms of general poisoning.

As Löffler stated in his original paper, inoculation of the healthy mucous membranes of various animals with pure cultures causes no lesion, but the formation of false membrane may

result when the surface is injured by scarification or otherwise. A similar result may be obtained when the trachea is inoculated after tracheotomy has been performed. In this case the surrounding tissues may become the seat of a blood-stained œdema, and the lymphatic glands become enlarged, the general picture resembling pretty closely that of laryngeal diphtheria. The membrane produced by such experiments is usually less firm than in human diphtheria, and the bacilli in the membrane are less numerous. Rabbits inoculated after tracheotomy often die, and Roux and Yersin were the first to observe that in some cases paralysis might appear before death.

Subcutaneous injection in guinea-pigs of diphtheria bacilli in a suitable dose produces death within thirty-six hours. At the site of inoculation there is usually a small patch of greyish membrane with some necrosis, whilst in the tissues around there is extensive inflammatory œdema, often associated with hæmorrhages, and there is also some swelling of the corresponding lymphatic glands. The internal organs show general congestion, the suprarenal capsules being especially reddened and often hæmorrhagic. The renal epithelium may show cloudy swelling, and there is often effusion into the pleural cavities. After injection the bacilli increase in number for a few hours, but multiplication soon ceases, and at the time of death they may be less numerous than when injected. The bacilli remain practically local, cultures made from the blood and internal organs usually giving negative results, though sometimes a few colonies may be obtained. If a non-fatal dose of a culture be injected, a local necrosis of the skin and subcutaneous tissue may follow at the site of inoculation.

In rabbits, after subcutaneous inoculation, results of the same nature follow, but these animals are less susceptible than guinea-pigs, and the dose requires to be proportionately larger. Roux and Yersin found that after intravenous injection the bacilli rapidly disappeared from the blood, and when 1 c.c. of a broth culture had been injected no trace of the organisms could be detected by culture after twenty-four hours; nevertheless the animals died with symptoms of general toxæmia, nephritis also being often present (cf. Cholera, p. 469). The dog and sheep are also susceptible to inoculation with virulent bacilli, but the mouse and rat enjoy a high degree of immunity.

An *intra-cutaneous method* of injection has been found to be of service in testing the virulence, and thus in the identification, of the diphtheria bacillus, especially when used in conjunction with the injection of antitoxin. Injection with a fine syringe

of a small amount of diphtheria bacilli into the superficial part of the skin in a guinea-pig produces a circumscribed swelling which is followed by superficial necrosis in from one to two days; whereas, if the animal has received previously an injection of, say, 250 units of antitoxin, the result is negative. The result is also negative (without antitoxin) in the case of an avirulent diphtheroid.

The following is the method as modified by Zingher and Soletsky. A twenty-four hours' growth on a tube of Löffler's serum is emulsified in 20 c.c. of normal saline, and of this 0·15 c.c. is injected intracutaneously into the abdominal wall of a guinea-pig. Four or even six injections of different strains can be carried out at the same time in the same animal. Similar injections are made in an animal previously treated by antitoxin, the antitoxin being introduced intracardially immediately before, or intraperitoneally twenty-four hours before.

Klein found that cats also were susceptible to inoculation. The animals usually die after a few days, and *post mortem* there is well-marked nephritis. He also found that after subcutaneous injection in cows, a vesicular eruption appeared on the teats of the udder, the fluid in which contained diphtheria bacilli. At the time of death the diphtheria bacilli were still alive and virulent at the site of injection. The most striking result of these experiments is that the diphtheria bacilli passed into the circulation and were present in the eruption on the udder. He considers that this may throw light on certain epidemics of diphtheria in which the contagion was apparently carried by the milk. Other observers, *e.g.*, Abbott, have, however, failed to obtain similar results. Dean and Todd, in investigating an outbreak of diphtheria traceable to a milk supply, found a vesicular eruption on the teats of the udder in which diphtheria bacilli were present. They, however, came to the conclusion that these bacilli were not the cause of the eruption, but were the result of a secondary contamination, probably from the saliva of the milkers. The existence of a true diphtheria infection in cows must still be considered doubtful. A case of true diphtheria in the horse has been described by Cobbett.

The Toxins of Diphtheria.—As in the above experiments the symptoms of poisoning, and ultimately a fatal result, occur when the bacilli are diminishing in number, or even after they have practically disappeared, Roux and Yersin inferred that the chief effects were produced by toxins, and this supposition they proved to be correct. They showed that broth cultures of three or four weeks' growth freed from bacilli by filtration were highly toxic. The filtrate when injected into guinea-pigs and other animals produces practically the same effects as the living bacilli; locally there is little fibrinous exudation but a considerable amount of inflammatory œdema, and, if the animal survive long enough, necrosis of the superficial tissues in varying degree may follow. The toxicity may be so great that ·005 c.c. or even less may be fatal to a guinea-pig in five days.

After injection either of the toxin or of the living bacilli, when the animals survive long enough, paralytic phenomena occasionally occur. The hind-limbs are usually affected first, the paralysis afterwards extending to other parts, though sometimes the fore-limbs and neck first show the condition. Sometimes symptoms of paralysis do not appear till two or three weeks after inoculation. After paralysis has appeared, a fatal result usually follows in the smaller animals, but in dogs recovery may take place. There is evidence that these paralytic phenomena are produced by toxone, as they specially occur when there is injected along with the toxin sufficient antitoxin to neutralise the more rapidly acting toxin proper. This toxone is supposed by Ehrlich to have a different toxic action, *i.e.*, a different toxophorous group (p. 195), from that of the ordinary toxin; it produces the late nervous phenomena, while its local action on the tissues is very slight. It also has a weaker affinity for antitoxin, and thus much of it may be left unneutralised. It is to be noted in this connection that paralytic symptoms are of not uncommon occurrence in the human subject after treatment with antitoxin, the explanation of which occurrence is probably the same as that just given. One point of much interest is the high degree of resistance to the toxin possessed by mice and rats. Roux and Yersin, for example, found that 2 c.c. of toxin, which was sufficient to kill a rabbit in sixty hours, had no effect on a mouse, whilst of this toxin even $\frac{1}{15}$ c.c. produced extensive necrosis of the skin of the guinea-pig.

Preparation of the Toxin.—The obtaining of a very active toxin in large quantities is an essential in the preparation of anti-diphtheritic serum. Certain conditions favour the development of a high degree of toxicity, namely, *a free supply of oxygen, the presence of a large proportion of peptone or albumin in the medium, and the absence of substances which produce an acid reaction.* In the earlier work a current of sterile air was made to pass over the surface of the medium, as it was found that by this means the period of acid reaction was shortened and the toxin formation favoured. This expedient is now considered unnecessary if an alkaline medium free from glucose is used, as in this no acid reaction is developed; it is then sufficient to grow the cultures in shallow flasks. The absence of glucose may be attained by the method described above (p. 79), or by using for the preparation of the meat extract flesh which is just commencing to putrefy (Spronck). L. Martin uses a medium composed of equal parts of freshly prepared peptone (by digesting pigs' stomachs with HCl at 35° C.), and glucose-free veal-bouillon. By this medium he has obtained a toxin of which $\frac{1}{600}$ c.c. is the fatal dose to a guinea-pig of 500 grms. Park and Williams and also Dean found that the amount of glucose present in ordinary beef is not sufficient to interfere with toxin formation, provided that a considerable amount of peptone, 2 per cent., be added, and the

medium be made sufficiently alkaline; after making it neutral to litmus they added to each litre of broth 7 c.c. of normal caustic soda solution. There is in all cases a period at which the toxicity reaches a maximum; Roux and Yersin found this period to be two to three weeks, but later observers find that in favourable conditions the greatest toxicity is reached about the tenth to twelfth day, sometimes even earlier. It may be added that the power of toxin-formation varies much in different races of the diphtheria bacillus, and that many may require to be tested ere one suitable is obtained.

Properties and Nature of the Toxin.—The toxic substance in filtered cultures is a relatively unstable body. When kept in sealed tubes in the absence of light, it may preserve its powers little altered for several months, but, on the other hand, it gradually loses them when exposed to the action of light and air. As will be shown later (p. 565), the toxin probably does not become destroyed, but its toxophorous group suffers a sort of deterioration, so that a toxoid is formed which has still the power of combining with antitoxins. Heating at 58° C. for two hours destroys the toxic properties in great part, but not altogether. When, however, the toxin is evaporated to dryness, it has much greater resistance to heat. One striking fact, discovered by Roux and Yersin, is that after an organic acid, such as tartaric acid, is added to the toxin the toxic property disappears, but it can be in great part restored by again making the fluid alkaline.

Guinochet found that toxin was formed by the bacilli when grown in urine with no proteid bodies present. After growth had taken place he could not detect protein bodies in the fluid, but, on account of the very minute amount of toxin present, their absence could not be excluded. Uschinsky also found that toxic bodies were produced by diphtheria bacilli when grown in a protein-free medium.[1] It follows from this that if the toxin is a protein, it may be formed by synthesis within the bodies of the bacilli. Brieger and Boer have separated from diphtheria cultures a toxic body which gives no protein reaction (*vide* p. 192). Whether or not diphtheria toxin is of proteid nature must, however, be considered to be a question not yet settled, though the probability is that it is so.

Toxic bodies have also been obtained from the tissues of those who have died from diphtheria. Roux and Yersin, by using a filtered watery extract from the spleen from very virulent cases of diphtheria, produced in animals death after wasting and paralysis, and also obtained similar results by employing the urine. The subject of toxic bodies in the tissues was, however,

[1] Uschinsky's medium has the following composition: water, 1000 parts; glycerin, 30–40; sodium chloride, 5–7; calcium chloride, ·1; magnesium sulphate, ·2–·4; di-potassium phosphate, ·2–·25; ammonium lactate, 6–7; sodium asparaginate, 3–4.

specially worked out by Sidney Martin. He separated from the tissues, and especially from the spleen, of patients who have died from diphtheria, by precipitation with alcohol, chemical substances of two kinds, namely, albumoses (proto- and deutero-, but especially the latter), and an organic acid. The albumoses, when injected into rabbits, especially in repeated doses, produce fever, diarrhœa, paresis, and loss of weight, with ultimately a fatal result. He further found that the paresis is due to well-marked changes in the nerves. Substances obtained from diphtheria membrane have an action like that of the bodies obtained from the spleen, but in higher degree. Martin considered that this is due to the presence in the membrane of an enzyme which has a proteolytic action within the body, resulting in the formation of poisonous albumoses.

Immunity.—This is described in the general chapter on Immunity. It is sufficient to state here that a high degree of immunity, against both the bacilli and their toxins, can be produced in various animals by gradually increasing doses either of the bacilli or of their filtered toxins (*vide* Chapter XXII.). As a result of the immunisation, antitoxins appear in the serum, and these are capable of protecting animals against infection either with diphtheria bacilli or their toxins. They also have curative effects in animals which are already the subjects either of infection or intoxication.

Therapeutic Effects of Diphtheria Antitoxin.—The use of this antitoxin for the prevention and treatment of diphtheria constituted the first great contribution of bacteriology to practical therapeutics. For the protection of an individual exposed to infection 500 units of antitoxin are administered by the subcutaneous route, and in a case of the established disease from 2000 to 4000 units, according to the severity of the symptoms. By the application of the method a very great diminution in the mortality has resulted. The diphtheria antitoxin came into general use about October 1894, and the statistics published by Behring towards the end of 1895 indicated results which have since been confirmed. In the Berlin Hospitals the average mortality for the years 1891–93 was 36·1 per cent., in 1894 it was 21·1 per cent., and in January–July 1895, 14·9 per cent. The objection that in some epidemics a very mild type of disease prevails is met by the fact that similar diminutions of mortality have occurred all over the world. Loddo collected the results of 7000 cases in Europe, America, Australia, and Japan, in which the mortality was 20 per cent. as compared with a former mortality in the same hospitals of 44 per cent. When the treat-

ment was coming into use it was observed that if during an epidemic the supply of serum failed, the mortality at once rose,—in two instances recorded it was doubled. It must here be remembered that from the spread of bacteriological knowledge the diagnosis of diphtheria is now much more accurate than formerly. Another effect of the antitoxic treatment has been that when tracheotomy is necessary the percentage of recoveries is now much higher, being 73 per cent. instead of 27 per cent. in a group of cases collected by the American Pediatric Society. In statistics from London fever hospitals, the recoveries after tracheotomy were 56·4 as compared with 32·1 per cent. previous to the introduction of antitoxin. A striking result in the same hospitals brought out by the statistics was a reduction of the death-rate in post-scarlatinal diphtheria from 50 per cent. to between 4 per cent. and 5 per cent. As the disease here occurred while the patient was under observation, the treatment was nearly always begun on the first day. It is a matter of prime importance that the treatment should be commenced whenever the disease is recognised clinically, and a bacteriological diagnosis should not be waited for. Behring showed that in cases treated on the first and second days of the disease the mortality was only 7·3 per cent., and this has been generally confirmed, whilst after the fifth day it was of little service to apply the treatment. In order to obtain such results, it cannot be too strongly insisted on that attention should be given to the dosage.

Variations in the Virulence of the Diphtheria Bacillus.—In cultures on serum the diphtheria bacilli retain their virulence fairly well, and strains which are active producers of toxin have been found to retain this property practically unchanged for several years. Roux and Yersin found that, when the bacilli were grown at an abnormally high temperature, namely, 39·5° C., and in a current of air, the virulence diminished so much that they became practically innocuous. They also found that the virulence could often be restored if the bacilli were inoculated into animals along with streptococci. If, however, the virulence had fallen very low, even the presence of the streptococci was insufficient to restore it. Further, in the case of freshly isolated avirulent organisms, otherwise like diphtheria bacilli, the general result is that attempts to render them virulent have failed. (The virulence is tested by the amount of living bacilli necessary to produce a fatal result on injection into a guinea-pig, and is to be distinguished from the power of producing toxin in a fluid medium; as pointed out by Dean, the two properties often do not correspond.) Arkwright has found that the

virulence of recently isolated strains varies enormously, as much as in a proportion of 1 to 400. Some non-virulent diphtheria bacilli have been found to produce small quantities of toxin; and in the case of others again, where no toxin-production can be demonstrated directly, the injection of a filtrate of a broth culture has given rise to antitoxin formation, though in small degree. These facts show how difficult it is to define a true diphtheria bacillus.

Diphtheria Carriers.—It has been known for some time that diphtheria bacilli may persist for considerable periods in the throats of those who have suffered from the disease, and repeated examinations may be necessary before these persons can be pronounced free from the organisms and thus devoid of danger to the community. In such circumstances the bacilli may become attenuated, but this does not appear to be usually the case. The bacillus may also be found in the throats of those who have been in contact with the patients, and accordingly these individuals may act as carriers of infection. This is no merely occasional occurrence, as the observations of Macdonald in this country and of Kenyoun in America, which taken together include the examination of over three thousand contacts, show that about 10 per cent. of those harboured the diphtheria bacillus. Some of the "carriers" suffer from slight indisposition, sore throat, etc., but others have no clinical symptoms at all. The carriers may be of all ages, and the bacilli obtained from them prove, in some instances, to be still virulent for weeks or even months after exposure to infection; in other instances, whilst morphologically and culturally possessing the characters of the diphtheria bacillus, they are devoid of virulence.

Identification of the Diphtheria Bacillus—Allied Organisms.

It is now recognised that the diphtheria bacillus is a member of a group of organisms with closely allied characters which are of common occurrence and have a wide distribution. The terms "pseudo-diphtheria bacilli" and "diphtheroid bacilli" have been applied in a loose way to organisms which resemble the diphtheria bacillus microscopically, especially as regards the beaded appearance. Such bacilli have been obtained from the mouth, ear, nose, skin, genital organs, and even from the blood in certain diseases. They are to be met with in conditions of health, and they have been obtained from many diverse morbid

conditions—from skin diseases, from coryza, from leprosy, from gun-shot wounds, and even from general paralysis of the insane. As has been found with other groups, the differentiation is a matter of considerable difficulty. Some are practically identical with the diphtheria bacillus both morphologically and culturally, and give the characteristic reaction with Neisser's stain; others, again, differ in essential particulars. The fermentative action on sugars (p. 404) has also been called into requisition as a means of distinguishing them, but the results obtained cannot be said to be of a definite character. The absence of the power of fermenting glucose may, however, be accepted in any particular case as sufficient to exclude the organism from being the diphtheria bacillus.

From what has been said it will be clear that the scientific differentiation of the organism may be a matter of great difficulty —even with the test for virulence, so many gradations are met with. With regard to the rules for practical guidance, there is general agreement as to the two following. In the first place, in cases of suspected diphtheria the obtaining of a bacillus in a serum culture from the throat, which has all the morphological and staining characters of the diphtheria bacillus, may be accepted as a positive result for all practical purposes. And further, most will agree that a similar rule should hold in the first instance with regard to bacilli obtained from the throats of immediate contacts. In the second place, a diphtheria-like bacillus obtained from another part of the body, with or without a lesion, should not be accepted as the diphtheria bacillus, however closely it resembles it, unless it is found on inoculation to produce the characteristic results. In view, however, of the fact that diphtheria-like bacilli without virulence are present in the throats of some healthy individuals, and may also be present along with virulent bacilli in cases of diphtheria, it appears to us that no one should be regarded as a carrier, dangerous to the community, unless the organism in question is proved to possess virulence. Such a rule rests on the assumption that quite avirulent bacilli do not give rise to infection and may be disregarded. The results of the accumulated experience of numerous observers, however, support such a view.

Ford Robertson and his co-workers have obtained from numerous cases of general paralysis of the insane cultures of a diphtheroid organism, which he considers is the chief agent in producing the condition of chronic intoxication underlying the disease. The organism has been obtained from various situations, including the central nervous system, but it seems to flourish specially in the respiratory and alimentary tracts. It closely resembles the diphtheria bacillus; the morphological and

cultural characters are indeed practically identical, but the diphtheroid bacillus is non-pathogenic to the guinea-pig. Robertson and Shennan found that when administered to rats by the alimentary tract it produced certain nervous symptoms which were associated with changes in the brain of the same order as those in general paralysis. Further research on this subject is still necessary.

The term "pseudo-diphtheria bacillus" is often restricted by writers to an organism frequently met with in the throat. This organism, which is also known as Hofmann's bacillus, merits a separate description.

Hofmann's Bacillus — Pseudo-Diphtheria Bacillus. — This organism, described by Hofmann in 1888, is probably the same as one observed by Löffler in the previous year, and regarded by him as being a distinct species from the diphtheria bacillus. The organism is a shorter bacillus than the diphtheria bacillus, with usually a single unstained septum running across it, though sometimes there may be more than one (Fig. 117). The typical beaded appearance is rarely seen, and the characteristic reaction with Neisser's stain is not given, though in old cultures a few granules which stain deeply may sometimes be found. It grows readily on the same media as the diphtheria bacillus, but the colonies are whiter and more opaque. It does not form acid from glucose or other sugars, and is non-pathogenic to the guinea-pig. Involution forms may sometimes be produced by it. It is usually a relatively easy matter to distinguish this organism from the diphtheria bacillus.

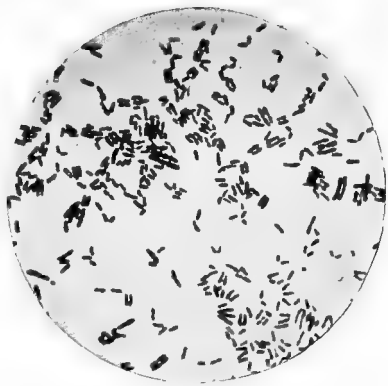

FIG. 117.—Pseudo-diphtheria bacillus (Hofmann's). Young agar culture. See also Plate III., Fig. 14. Stained with thionin-blue. ×1000.

Hofmann's bacillus is of comparatively common occurrence in the throat in normal as well as diseased conditions, including diphtheria; it seems to be specially frequent in poorly nourished children of the lower classes. Cobbett found it 157 times in an examination of 692 persons examined, of whom 650 were not

suffering from diphtheria. Boycott's statistics show that the time of its maximum seasonal prevalence precedes that of the diphtheria bacillus. To what extent, if any, it is responsible for pathological changes in the throat, must be considered a question which is not yet settled. Hewlett and Knight have found evidence that a true diphtheria bacillus may assume the characters of Hofmann's bacillus, but attempts to effect the transformation have met with negative results in the hands of other observers. The general opinion is that the two organisms are distinct species with comparatively easily distinguished characters.

Xerosis Bacillus.—This term has been given to an organism first observed by Kuschbert and Neisser in xerosis of the conjunctiva, and which has been since found in many other affections of the conjunctiva and also in normal conditions. Morphologically it is practically similar to the diphtheria bacillus, and even in cultures presents very minor differences; it, however, grows more slowly on serum, and its colonies have a tougher consistence and a more irregular margin. It is non-virulent to animals, and does not produce an acid reaction in glucose bouillon, or does so to only a slight extent; in this way it can be distinguished from the diphtheria bacillus. It is still doubtful whether it is pathogenic to the human subject. Its morphological characters are shown in Fig. 118.

Action of the Diphtheria Bacillus—Summary.—From a study of the morbid changes in diphtheria and of the results produced experimentally by the bacillus and its toxins, the following summary may be given of its action in the body. Locally, the bacillus produces inflammatory change with fibrinous exudation, but at the same time cellular necrosis is also an outstanding feature. Though false membranes have not been produced by the toxins, a necrotic action may result when these are injected subcutaneously. The toxins also act upon the blood vessels, and hence œdema and tendency to hæmorrhage are produced; this action on the vessels is also exemplified by the general congestion of organs. The hyaline change in the

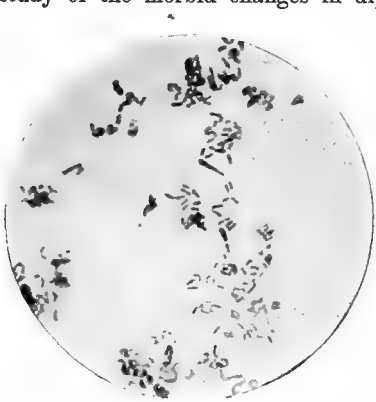

FIG. 118.—Xerosis bacillus from a young agar culture. ×1000.

walls of arterioles and capillaries, so often met with in diphtheria, is another example of the action of the toxin. The toxins have also a pernicious action on highly developed cells and on nerve fibres. Thus in the kidney cloudy swelling occurs, which may be followed by actual necrosis of the secreting cells, and along with these changes albuminuria is present. The action is also well seen in the case of the muscle fibres of the heart, which may undergo a sort of hyaline change, followed by granular disintegration and associated with leucocytic infiltration. These changes are of great importance in relation to heart failure in the disease. Changes of a somewhat similar nature have been observed in the nerve cells of the central nervous system, those lying near the capillaries, it is said, being affected first. There is also the striking change in the peripheral nerves, which is shown first by the disintegration of the medullary sheaths as already described. It is, however, still a matter of dispute to what extent these nerve lesions are of primary nature or secondary to changes in the nerve cells.

Methods of Diagnosis.—These include: (*a*) *Microscopical Examination.*—For microscopical examination it is sufficient to tease out a piece of the membrane with forceps and rub it on a cover-glass; if it be somewhat dry, a small drop of normal saline should be added. The films are then dried in the usual way, and stained with any ordinary basic stain, though methylene-blue is on the whole to be preferred, used either as a saturated watery solution or in the form of Löffler's solution. After staining for two or three minutes, the films are washed in water, dried, and mounted. As a rule no decolorising is necessary, as the blue does not overstain. Neisser's stain (p. 114) may also be used with advantage, although it is to be noted that sometimes in a secretion the diphtheria bacillus does not react typically to this stain. Any secretion from the pharynx or other part is to be treated in the same way. Diagnosis by the microscopic examination is now little used, but it is sometimes justified in cases of urgency, though only in the hands of an experienced observer. In some cases the bacilli are present in characteristic form in such numbers as to leave no doubt in the matter.

(*b*) *Cultivation.*—For this purpose a piece of the membrane should be separated by forceps from the pharynx or other part when that is possible. It should be then washed well in a tube containing sterile water, most of the surface impurities being removed in this way. A fragment is then fixed in a platinum loop by means of sterile forceps, and a series of stroke cultures

is made on the surface of any of the media mentioned (p. 403), the same portion of the membrane being always brought into contact with the surface. More usually a swab taken from the pharynx is smeared over the medium in a similar manner. The tubes are then incubated at 37° C., and are ready for examination in eighteen to twenty-four hours. A representative sample of the whole growth is obtained by rubbing a platinum loop over the surface; films are made from this, stained, and examined in the usual way, Neisser's stain being also applied. Any doubtful organism should be tested by growing for two to three days in glucose peptone water, tinted with neutral-red, to which a few drops of sterile serum have been added to aid growth. If no acid is produced the organism may be rejected; if acid is formed, animal tests should be carried out. For the obtaining of a pure culture the telluric acid medium (p. 52) will be found of great service.

(*c*) *Inoculation.*—The bacillus in question should be grown in bouillon for two to three days, and then a guinea-pig inoculated with 1 c.c. (This is the most suitable method, though it is not strictly a test of pure virulence, the result being to some extent due to toxin produced in the culture.) If the animal dies with the characteristic lesions, further tests may be made with smaller doses. The intra-cutaneous (p. 407) method may also be used. For interpretation of results, *vide* p. 414.

CHAPTER XVII.

TETANUS[1]: CONDITIONS CAUSED BY OTHER ANAEROBIC BACILLI.

Introductory.—Tetanus is a disease which in natural conditions affects chiefly man and the horse. Clinically it is characterised by the gradual onset of general stiffness and spasms of the voluntary muscles, commencing in those of the jaw and the back of the neck, and extending to all the muscles of the body. These spasms are of a tonic nature, and, as the disease advances, succeed each other with only a slight intermission of time. There are often, towards the end of a case, fever and rise of respiration and pulse-rate. The disease is usually associated with a wound received ordinarily from four to fourteen days previously, and which has been defiled by earth or dung. The disease is, in the majority of cases, fatal.

Historical.—The general association of the development of tetanus with the presence of wounds, though these might be very small, suggested that some infection took place through the latter, but for long nothing was known as to the nature of this infection. Carle and Rattone in 1884 announced that they had produced the disease in a number of animals by inoculation with material from a wound in tetanus. They thus demonstrated the transmissibility of the disease. Nicolaier (1885) infected mice and rabbits with garden earth, and found that many of them developed tetanus. Suppuration occurred in the neighbourhood of the point of inoculation, and in this pus, besides other organisms, there was always present, when tetanus had occurred, a bacillus having certain constant microscopic characters. Inoculation of fresh animals with such pus reproduced the disease. Nicolaier's attempts at its isolation by the ordinary gelatin plate-culture method were, however, unsuccessful. He succeeded in getting it to grow in liquid blood serum, but always in mixture with other organisms. Infection of animals with such a culture

[1] This disease is not to be confused with the "tetany" of infants, which in its essential pathology differs from tetanus (*vide* Frankl-Hochwart, "Die Tetanie der Erwachsenen," Vienna, 1907). This remark, of course, does not exclude the occurrence of true tetanus in very young subjects, in whom, in fact, infection frequently takes place, often at the umbilicus.

produced the disease. These results were confirmed by Rosenbach, who, though failing to obtain a pure culture, cultivated the other organisms present, and inoculated them, but with negative results. He further pointed out, as characteristic of the bacillus, its development of terminal spores. In 1889, Kitasato succeeded in isolating from the local suppuration of mice inoculated from a human case, several bacilli, only one of which, when injected in pure culture into animals, caused the disease, and which was now named the b. tetani. This organism is the same as that observed by Nicolaier and Rosenbach. Kitasato found that the cause of earlier culture failures was the fact that it could only grow in the absence of oxygen. The pathology of the disease was further elucidated by Faber, who, having isolated bacterium-free poisons from cultures, reproduced the symptoms of the disease.

Bacillus Tetani.—If in a case of tetanus naturally arising in man, there be a definite wound with pus formation or necrotic change, the bacillus tetani may be recognised in film preparations from the pus, if the characteristic spore formation has occurred (Fig. 119). If, however, the tetanus bacilli have not formed spores, they appear as somewhat slender rods, without presenting any characteristic features. There is usually present in such pus a great variety of other organisms—cocci and bacilli. The characters of the bacillus are, therefore, best studied in cultures. It is then seen to be a slender organism, usually about ·4 μ to 5 μ in length and ·4 μ in thickness, with somewhat rounded ends. Besides occurring as shorter rods it also develops filamentous forms, the latter being more common in fluid media. It stains readily by any of the usual stains and also by Gram's method. A feature in it is the uniformity with which the protoplasm stains. It is very slightly motile, and its motility can be best studied in an anaerobic hanging-drop preparation. When stained by the special methods already described, it is found to possess numerous delicate flagella attached both at the sides and at the ends (Fig. 120). These flagella, though they may be of considerable length, are usually curled up close to the body of the bacillus. The formation of flagella can be best studied in preparations made from surface anaerobic cultures (p. 69). As is the case with many other anaerobic flagellated bacteria, the flagella, on becoming detached, often become massed together in the form of spirals of striking appearance (Fig. 121). At incubation temperature b. tetani readily forms spores, and then presents a very characteristic appearance. The spores are round, and in diameter may be three or four times the thickness of the bacilli. They are developed at one end of a bacillus, which thus assumes what is usually described as the "drumstick" form (Figs. 119, 122). In a specimen stained with a watery solution of gentian-violet or

methylene-blue, the spores are uncoloured except at the periphery, so that the appearance of a small ring is produced; if a powerful stain such as carbol-fuchsin be applied for some time, the spores become deeply coloured like the bacilli. Further, especially if the preparation be heated, many spores may become free from the bacilli in which they were formed.

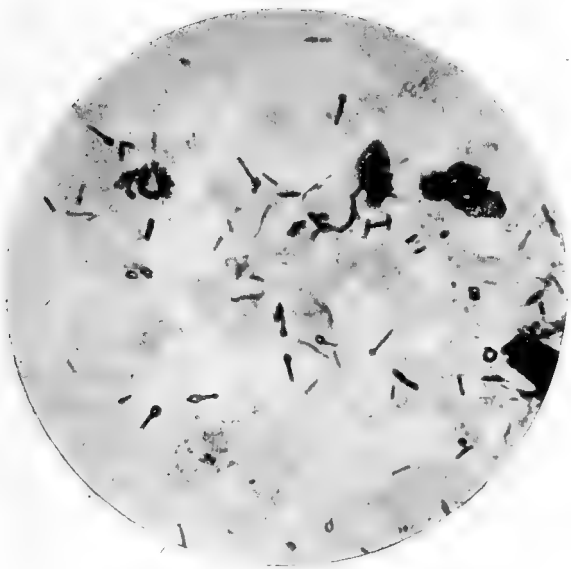

FIG. 119.—Film preparation of discharge from wound in a case of tetanus, showing several tetanus bacilli of "drumstick" form. (The thicker bacillus present is not a tetanus bacillus, but a putrefactive anaerobe which was obtained in pure culture from the wound.)

Stained with gentian-violet. ×1000.

Isolation.—The isolation of the tetanus bacillus is somewhat difficult. By inoculation experiments in animals, its natural habitat has been proved to be garden soil, and especially the contents of dung-heaps, where it probably leads a saprophytic existence, though its function as a saprophyte is unknown. It also occurs in the dust of houses, on the skin and in the intestines of many—especially of herbivorous—animals. From such sources and from the pus of wounds in tetanus,

occurring naturally or experimentally produced, it has been isolated by means of the methods appropriate for anaerobic bacteria. The best methods for dealing with such pus are as follows :--

(1) The principle is to take advantage of the resistance of the spores of the bacillus to heat. A sloped tube of inspissated serum or a deep tube of glucose agar is inoculated and incubated anaerobically at 37° C. for forty-eight hours, at the

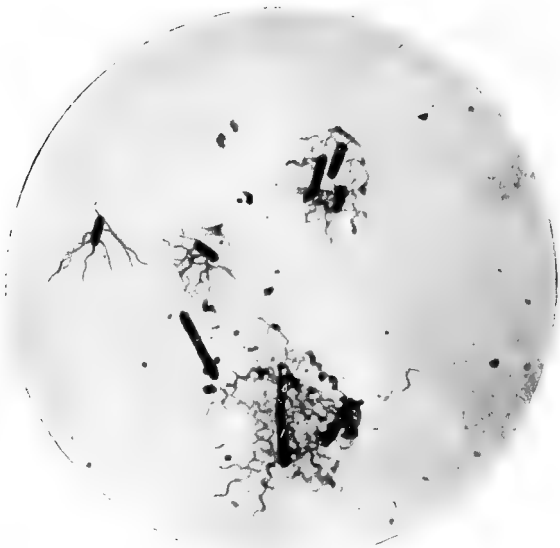

FIG. 120.—Tetanus bacilli, showing flagella. Stained by Rd. Muir's method. ×1000.

end of which time numerous spore-bearing bacilli can often be observed microscopically. The culture is then kept at 80° C. for from three-quarters to one hour, with the view of killing all organisms except those which have spored. From such material agar anaerobic plates are prepared by one of the methods described on pp. 62–65. Kitasato compares the colonies in gelatin plates to those of the b. subtilis. They consist of a thick centre with shoots radiating out on all sides. They liquefy the gelatin more slowly than the b. subtilis. This method of isolation is not always successful, partly because along with the tetanus

bacilli, both in its natural habitats outside the body and in the pus of wounds, other spore-forming obligatory and facultative anaerobes occur, which grow faster than the tetanus bacillus, and thus overgrow it.

(2) If in any discharge the spore-bearing tetanus bacilli be seen on microscopic examination, then a method of isolation based on the same principle as the last may be adopted. Inoculations with different dilutions of the suspected material are made in half a dozen deep tubes of glucose bouillon, previously raised to a temperature of 100° C. After inoculation they are again placed in boiling water and kept for varying times, say for half a minute, for one, three, four, five, and six minutes respectively. They are then plunged in cold water till cool, and thereafter placed in the incubator at 37° C., in the hope that in one or other of the tubes all the organisms present will have been killed, except the tetanus spores which can develop in pure culture. A series of deep glucose agar tubes may also be inoculated from the series of bouillon tubes.

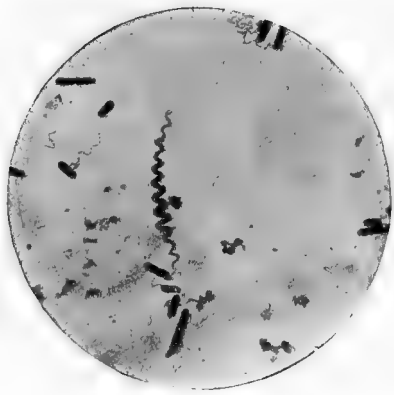

FIG. 121.—Spiral composed of numerous twisted flagella of the tetanus bacillus. Stained by Rd. Muir's method. ×1000.

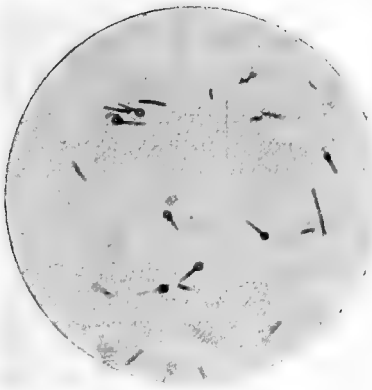

FIG. 122.—Tetanus bacilli; some of which possess spores. From a culture in glucose agar, incubated for three days at 37° C. See also Plate IV., Fig. 20. Stained with carbol-fuchsin. ×1000.

(3) Anaerobic plates may be prepared directly from the discharge of the wound. The isolation of the tetanus bacillus is in many cases a difficult matter, and several methods should always be tried.

Characters of Cultures.—Pure cultures having been obtained, sub-cultures can be made in deep upright glucose gelatin or agar tubes. In deep *glucose gelatin* (in which growth is often very difficult to obtain) there commences, an inch or so below the surface, a growth consisting of fine straight threads, rather longer in the lower than in the upper parts of the tube, radiating out from the needle track (Fig. 123). Slow liquefaction of the gelatin takes place, with slight gas formation. In *agar* the growth is somewhat similar, consisting of small nodules along the needle track, with irregular short offshoots passing out into the medium (Fig. 131, A). There is slight formation of gas, but, of course, no liquefaction. On anaerobic agar plates colonies have under a low power a feathery outline (Fig. 124). Growth also occurs in *blood serum* and also in *glucose bouillon* and Robertson's *bullock's heart medium* under anaerobic conditions. There is in it at first a slight turbidity, and later a thin layer of a powdery deposit on the walls of the vessel. All the cultures give out a peculiar burnt odour of rather unpleasant character. In making sub-cultures on fluid media a considerable amount of the original growth should be used for the inoculation.

FIG. 123.—Stab culture of the tetanus bacillus in glucose gelatin, showing the lateral shoots (after Kitasato). Natural size.

Conditions of Growth, etc.—The b. tetani grows best at 37° C. The minimum growth temperature is about 14° C., and below 22° C. growth takes place very slowly. Growth takes place only in the absence of free oxygen, the organism being an *anaerobe.* Sporulation may commence at the end of twenty-four hours in cultures grown at 37° C.—much later at lower temperatures. Like other spores, those of tetanus are extremely resistant. They can usually withstand boiling for five minutes, and can be kept in a dry condition for many months without being killed or

losing their virulence. They have also high powers of resistance to antiseptics.

Pathogenic Effects.—The proof that the b. tetani is the cause of tetanus is complete. It can be isolated in pure culture, and when re-injected in pure culture it reproduces the disease. It may be impossible to isolate it from some cases of the disease, but the cause of this very probably is the small numbers in which it sometimes occurs.

(*a*) *The Disease as arising naturally.*—The disease occurs naturally, chiefly in horses and in man. Other animals may, however, be affected. In different animal species variations in

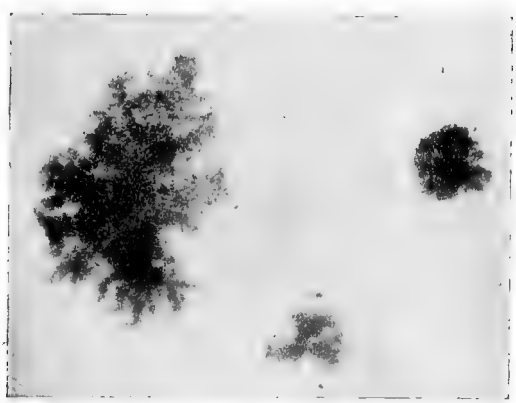

FIG. 124.—Colonies of the tetanus bacillus on anaerobic agar plates, seven days old. ×50.

the clinical progress of the disease are observed. In man and in the horse the spasms early affect the extensor muscles of the trunk, while in other animals they may first appear in the muscles neighbouring on the site of infection. There is in most cases a definite wound, often of a ragged character, which has either been made by an object soiled with earth or dung, or which has become contaminated with these substances. There is often a purulent or fœtid discharge, though this may be absent. In tetanus following clean operation wounds, catgut ligatures may be the source of infection. Microscopic examination of sections may show at the edges of the infected wound necrosed tissue in which the tetanus bacilli may be very numerous. If a scraping from the wound be examined micro-

scopically, bacilli resembling the tetanus bacillus may be recognised. Care must be taken, however, to distinguish it from other thicker bacilli with oval spores placed at a short distance from their extremities, such forms being common in earth, etc., and also met with in contaminated wounds. It is important to note that the wound through which infection has taken place may be very small, in fact, may consist of a mere abrasion. In some cases, especially in the tropics, it may possibly be merely the bite of an insect. In many parts of the world infection through the umbilicus originates a high mortality from the disease in newly born infants. The absence in many cases of a definite channel of infection has given rise to the term "idiopathic" tetanus. There is, however, practically no doubt that all such cases are true cases of tetanus, and that in all of them the cause is the b. tetani. The latter has also been found in the bronchial mucous membrane in some cases of the so-called rheumatic tetanus, the cause of which is usually said to be cold; infection of the intestinal mucosa may also occur.

During the present war the clinical type of tetanus seen in the wounded has been modified in consequence of the wide application of the prophylactic injection of anti-tetanus serum (*vide infra*). In the first place there has been a tendency to the prolongation of the incubation period, instances where this has extended to many months being not uncommon. In such cases there has usually been an unhealed septic wound, often containing foreign bodies, and the attack of tetanus may be precipitated by operative procedures; sometimes the wound has healed and tetanus has followed operation for the removal of foreign bodies in the tissues. Again the disease tends to assume the type seen in some animals, the muscles in the neighbourhood of the wound being first affected; local hardness and stiffness, pain, and exaggeration of local reflexes have thus often been the first, and sometimes the only, clinical phenomena. Such cases of tetanus are also apparently more amenable to treatment with antitetanus serum.

The pathological changes found *post mortem* are not striking. There may be hæmorrhages in the muscles, which have been the subject of the spasms. These are probably due to mechanical causes. It is in the nervous system that we naturally look for the most important lesions. Here there is ordinarily a general redness of the grey matter, and the most striking feature is the occurrence of irregular patches of slight congestion which are not limited particularly to grey or white matter, or to any tract of the latter. These patches are usually best marked in the grey

matter of the medulla and pons. Microscopically there is little of a definite nature to be found. There is congestion, and there may be minute hæmorrhages in the areas noted by the naked eye. The ganglion cells may show appearances which have been regarded as degenerative in nature, and similar changes have been described in the white matter. The only marked feature is thus a vascular disturbance in the central nervous system, with a possible tendency to degeneration in its specialised cells. Both of these conditions are probably due to the action of the toxins of the bacillus. In the case of the cellular degenerations the cells have been observed to return to the normal under the curative influence of the antitoxins (*vide infra*). In the other organs of the body there are no constant changes.

We have said that the general distribution of pathogenic bacteria throughout the body is probably a relative phenomenon, and that bacteria usually found locally may occur generally, and *vice versa*. With regard to the tetanus bacillus, it is, however, probably the case that very rarely, if ever, are the organisms found anywhere except in the local lesion.

(*b*) *The Artificially-produced Disease.*—The disease can be communicated to animals by any of the usual methods of inoculation, but does not arise in animals fed with bacilli, whether these contain spores or not. Kitasato found that pure cultures, injected subcutaneously or intravenously, caused death in mice, rats, guinea-pigs, and rabbits. In mice, symptoms appear in a day, and death occurs in two or three days, after inoculation with a loopful of a bouillon culture. The other animals mentioned require larger doses, and death does not occur so rapidly. Usually in animals injected subcutaneously the spasms begin in the limb nearest the point of inoculation. In the case of intravenous inoculation the spasms begin in the extensor muscles of the trunk, as in the natural disease in man. In intraperitoneal injection spasms in the muscles controlled by the splanchnic system are an outstanding feature. After death there is found slight hyperæmia without pus formation, at the seat of inoculation. The bacilli diminish in number, and may be absent at the time of death. The organs generally show little change.

Kitasato stated that in his earlier experiments the quantity of culture medium injected along with the bacilli already contained enough of the poisonous bodies formed by the bacilli to cause death. The symptoms came on sooner than by the improved method mentioned below, and were, therefore, due to the toxins already present. In his subsequent work, therefore, he employed

splinters of wood soaked in cultures in which spores were present, and subsequently subjected for one hour to a temperature of 80° C. The latter treatment not only killed all the vegetative forms of the organism, but, as we shall see, was sufficient to destroy the activity of the toxins. When such splinters are introduced subcutaneously, death results by the development of the spores which they carry. In this way he completed the proof that the bacilli by themselves can form toxins in the body and produce the disease. Further, if a small quantity of garden earth be placed under the skin of a mouse, death from tetanus takes place in a great many cases. [Sometimes, however, in such circumstances death occurs without tetanic symptoms, and is not due to the tetanus bacillus but to the bacillus of malignant œdema, which also is of common occurrence in the soil (*vide infra*).] By such experiments, supplemented by the culture experiments mentioned, the natural habitats of the b. tetani, as given above, have become known.

The Toxins of the Tetanus Bacillus.—The tetanus bacillus being thus accepted as the cause of the disease, we have to consider how it produces its pathogenic effects.

Almost contemporaneously with the work on diphtheria an attempt was made with regard to tetanus to explain the general symptoms by the soluble poisons of the bacillus. The earlier results, in which certain bases, tetanin and tetanotoxin, were said to have been isolated, have only a historic interest, as they were obtained by faulty methods. In 1890, Brieger and Fraenkel announced that they had isolated a *toxalbumin* from tetanus cultures, and this body was independently discovered by Faber in the same year. Brieger and Fraenkel's body consisted practically of an alcoholic precipitate from filtered cultures in bouillon, and was undoubtedly toxic. Within recent years such attempts to isolate tetanus toxins in a pure condition have practically been abandoned, and attention has been turned to the investigation of the physiological effects either of the crude toxin present in filtered ordinary bouillon cultures grown under anaerobic conditions, or of the precipitate produced from the same by ammonium sulphate (*cf.* p. 190).

The toxic properties of bacterium-free filtrates of pure cultures of the b. tetani were investigated in 1891 by Kitasato. This observer found that when the filtrate, in certain doses, was injected subcutaneously or intravenously into mice, tetanic spasms developed, first in muscles contiguous to the site of inoculation, and later all over the body. Death resulted. He found that guinea-pigs were more susceptible than mice, and rabbits less so. In order that a strongly toxic bouillon be produced, it must

originally have been either neutral or slightly alkaline. Kitasato further found that the toxin was easily injured by heat. Exposure for a few minutes at 65° C. destroyed it. It was also destroyed by twenty minutes' exposure at 60° C., and by one and a half hours' at 55° C. Drying had no effect. It was, however, destroyed by various chemicals such as pyrogallol, and also by sunlight.

To prepare the toxin, freshly made veal bouillon not too long autoclaved should be used and a massive inoculation, preferably from a fluid culture, practised. Individual strains of the bacillus differ in their capacity for producing toxin. The culture must be incubated under anaerobic conditions and the maximum toxicity is developed in from ten to fifteen days. Behring pointed out that after the filtration of cultures containing toxin, the latter may very rapidly lose its power, and in a few days may only possess $\frac{1}{100}$th of its original toxicity. This is due to such factors as temperature and light, and especially to the action of oxygen. Toxins should thus have a layer of toluol floated on the surface and be kept in a cool, dark place. The effect of harmful agents on the crude toxin is apparently to cause a degeneration of the true toxin so as to form what it is convenient at present to call *toxoids*, similar to those produced in the case of diphtheria toxin, and it is also true here that the toxoids while losing their toxicity may still retain their power of producing immunity against the potent toxin. Further, altogether apart from the occurrence side by side in the crude toxin of strong and weak poisons, it has been shown that such crude toxin may contain different varieties of toxic substances. Ehrlich showed that besides the predominant spasm-producing toxin (called by him *tetanospasmin*), there often exists in crude toxin a poison capable of producing the solution of certain red blood corpuscles. This hæmolytic agent he called *tetanolysin*. It does not occur in all samples of crude tetanus toxin, nor is it found when a bouillon culture of the bacillus is filtered through porcelain. To obtain it, the fresh culture must be treated by ammonium sulphate, as described in the method of obtaining concentrated toxins (p. 190). Tetanolysin also has the power of originating an antitoxin, so that certain antitetanic sera can protect red blood corpuscles against its action. Madsen, studying the interactions of this anti-tetanolysin with the tetanolysin, has shown that phenomena can be demonstrated similar to those noted by Ehrlich as occurring with diphtheria toxin, and which the latter interpreted as indicating the presence of degenerated toxins (toxoids) in the crude poison. With

tetanus as with diphtheria toxin, the action of an acid is to cause an apparent disappearance of toxicity, but if before a certain time has elapsed the acid be neutralised by alkali, then a degree of the toxicity returns.

As with other members of the group, nothing is known of the nature of tetanus toxin. Uschinsky has found that the tetanus bacillus can produce its toxin when growing in a fluid containing no proteid matter. The toxin may thus be formed independently of the breaking up of the proteins on which the bacillus may be living, though the latter has a digestive action on proteins. There is evidence that peptic digestion and toxin formation are due to different vital processes on the part of the tetanus bacillus.

The toxin is one of the most powerful poisons known. Even with a probably impure toxalbumin Brieger found that the fatal dose for a mouse was ·0005 of a milligramme. If the susceptibility of man be the same as that of a mouse, the fatal dose for an average adult would have been ·23 of a milligramme. Animals differ very much in their susceptibilities to the action of tetanus toxin. According to v. Lingelsheim, if the minimal lethal dose per gramme weight for a horse be taken as unity, that for the guinea-pig would be 6 times the amount, the mouse 12, the goat 24, the dog about 500, the rabbit 1800, the cat 6000, the goose 12,000, the pigeon 48,000, and the hen 360,000.

A striking feature of the action of tetanus toxin is the occurrence of an incubation period between the introduction of the toxin into an animal's body and the appearance of symptoms. This varies according to the species of animal employed, the path of infection, and the dose given. In the guinea-pig it is from thirteen to eighteen hours, in the horse five days, and the incubation is shorter when the poison is introduced into a vein than when injected subcutaneously. In man the period between the receiving of an injury and the appearance of tetanic symptoms is usually from two to fourteen days, but this period may be lengthened, and the bacilli may remain a considerable time shut up in a wound before producing effects. The longer the incubation period, the more favourable is the prognosis, and in chronic cases spontaneous recovery is not uncommon.

With regard to the *action* of the toxin, it has been shown to have no effect on the sensory or motor endings of the nerves. It acts solely as an exciter of the motor cells in the spinal cord, the nerve storm being often precipitated by peripheral irritation. The motor cells in the pons and medulla are also affected, and to a much greater degree than those in the cerebral cortex.

When injected subcutaneously the toxin is partly absorbed into the nerves, and thence finds its way to that part of the spinal cord from which these nerves spring. This explains the fact that in some animals the tetanic spasms appear first in the muscles of the part in which the inoculation has taken place. In man under ordinary circumstances the first symptoms appear in the neck. After subcutaneous injection of toxin, part finds its way into the blood stream, and if infected animals be killed during the incubation period there is often evidence of toxin in the blood and solid organs. In the guinea-pig there is little doubt that tetanus toxin has an affinity solely for the nervous system. In other animals, *e.g.*, the rabbit, an affinity may exist in other organs, and the fixation of the poison in such situations may give rise to no recognisable symptoms. In such an animal as the alligator, it is possible that while some of its organs have an affinity for tetanus toxin its nervous system has none. Tetanus toxin introduced into the stomach or intestine is not absorbed, but to a large extent passes through the intestine unchanged. Evidence that any destruction takes place is wanting.

Marie and Morax shed some important light on the mode of action of tetanus toxin in studying the path of absorption when the toxin was injected into the muscles of the hind-limb. The sciatic nerve in a rabbit was cut near the spinal cord and toxin introduced into the muscles of the same side; after some hours the nerve was excised and introduced into a mouse—the animal died of tetanus. But if the nerve were cut near the muscles the proximal part did not contain toxin, though no doubt it had been surrounded by lymph containing toxin. If the same experiment were performed and an excess of toxin injected into the other limb, still only the nerve which was left in connection with the muscle showed evidence of the presence of toxin. From this it was deduced that the toxin was absorbed by the end-plates in the muscle and not from the lymphatics surrounding the nerve. The absorption by the nerve was fairly rapid, as one hour after injection the toxin was present in it, and the toxin was shown to be exclusively centripetal in its flow. Further observations were made on this subject by Meyer and Ransom, who found that toxin is only absorbed by the motor filaments of a nerve, for while tetanus could be produced by injection into a mixed nerve like the sciatic, the introduction of a lethal dose into such a sensory nerve as the infra-orbital was not followed by disease symptoms. If a small dose of toxin be injected into the sciatic nerve, it reaches the corresponding motor cells of the cord,

and a local tetanus of the muscles supplied by the nerve results. With a larger dose the poison passes across the commissure to the corresponding cells of the other side, and if still further excess is present it passes up the cord to higher centres. The affection of such higher centres can be prevented by section of the cord. Meyer and Ransom hold that when toxin is injected subcutaneously or intravenously, it only acts by being absorbed by the end-plates in muscles and thence passes to the cord, and they consider that the incubation period is to be explained by the time taken for this extended passage to occur; in the larger animals, where the nerve path is longest, the incubation period is also longest. When intravenous injection is practised, the occurrence of tetanus in a part of the body can be precipitated by the injection of a drop of normal saline into the corresponding part of the cord—sufficient injury being thus caused to allow the toxin in the surrounding lymph to obtain access to the nervous elements. With regard to the action of tetanus toxin, Meyer and Ransom believe that there is a double effect on the nerve cells—first, an exaggeration of the normal tonus, which accounts for the continuous stiffness of the muscles; and secondly, an increase in reflex irritability, which is a prominent factor in the recurring spasms. While no absorption of toxin takes place by sensory filaments, they have found evidence of affection of the sensory apparatus in the occurrence of what they call *tetanus dolorosus*. This is a great hyperæsthesia and a paroxysmal hyperalgesia which can be caused by injecting toxin into the spinal cord or into a sensory root on the spinal side of the posterior root ganglion. These symptoms are unaccompanied by motor spasms, but the animal may die from exhaustion. The same observers, in investigating the action of antitoxin, found that its injection into a mixed nerve could prevent toxin from passing up to the cord, but that if antitoxin were injected even in great excess intravenously, and a short time thereafter toxin were introduced into a nerve, death was not prevented. This they attribute to the fact that antitoxin can only neutralise the toxin which is still circulating in the blood. This is a very far-reaching conclusion, as it throws doubt on what has been held to be a possibility, namely, that toxin can be actually detached from cells in which it is already anchored. But a still more significant observation was made, for in one case of an animal actively immunised against tetanus, and which contained in its serum a considerable quantity of antitoxin, the injection of toxin into the sciatic nerve was followed by tetanus. This would appear to militate against Ehrlich's position that

antitoxin is manufactured in the cells which are sensitive to the toxin (see Immunity).

Roux and Borrel, in injecting tetanus toxin into the brain itself, found that the ordinary type of the disease was not produced, but that what they called "cerebral tetanus" occurred. This consisted of general unrest, symptoms of a psychic character (apparent hallucinations, fear, etc.), and epileptiform convulsions. Death took place in from twelve to twenty hours, without any true tetanic spasms. In this manifestation of tetanus, the incubation period was much shorter than with subcutaneous injection, and the fatal dose was one twenty-fifth of the minimal subcutaneous dose. In the light of what has been already said, these results would seem to indicate a special effect of the toxin when brought into direct contact with the protoplasm of the brain cells.

We have seen that unless suitable precautions are adopted in experiments with tetanus cultures in animals, death results not from the multiplication of the bacilli, but from an intoxication with toxin previously existent in the fluid in which the bacilli have been growing. According to Vaillard, if spores rendered toxin-free, by being kept for a sufficient time at 80° C., are injected into an animal, death does not take place. It was found, however, that such spores can be rendered pathogenic by injecting along with them such chemicals as lactic acid, by injuring the seat of inoculation so as to cause effusion of blood, by fracturing an adjacent bone, by introducing a mechanical irritant such as soil or a splinter of wood (as in Kitasato's experiments), or by the simultaneous injection of other bacteria such as the *staphylococcus pyogenes aureus*. These facts, especially the last, throw great light on the disease as it occurs naturally, for tetanus results especially from wounds which have been accidentally subjected to conditions such as those enumerated. Kitasato now holds that in the natural infection in man, along with tetanus spores, the presence of foreign material or of other bacteria is necessary. Spores alone or tetanus bacilli without spores die in the tissues, and tetanus does not result.

Immunity against Tetanus.—Antitetanic Serum.—The artificial immunisation of animals against tetanus received much attention, especially from Behring and Kitasato in Germany, and Tizzoni and Cattani in Italy. The former observers found that a degree of immunity could be conferred by the injection of very small and progressively increasing doses of the tetanus toxin. Subsequent work has shown that the richer a crude toxin is in modifications of the true toxin, the more useful it is for immunisa-

tion procedures. In fact it is doubtful if small animals can be immunised at all by fresh filtrates. In some cases the injection of non-lethal doses instead of commencing an immunity actually increases the susceptibility of the animal, and this may be related to the development of supersensitiveness to proteids generally (see "Anaphylaxis" under Immunity). More successful in producing immunity are the methods of accompanying the early injections of crude toxin with the subcutaneous introduction of small doses of iodine terchloride, or of using toxin which has been acted on with iodine terchloride or with iodine itself. Living cultures attenuated in various ways, *e.g.*, by heat, have also been used. By any of these methods susceptible animals can be made to acquire great immunity against large doses of tetanus toxin, and also against living bacilli. Immunity thus acquired remains in existence for a very long time. The serum of such immune animals possesses the capacity of protecting animals susceptible to the disease against a subsequent injection of a fatal dose of tetanus bacilli or toxin. Further, if injected subsequently to infection, the serum can in certain cases prevent a fatal result, even when symptoms have begun to appear. The degree of success attained depends, however, on the shortness of the time which has elapsed between the injection of the bacilli or of toxin and the injection of the serum. In animals where symptoms have fully manifested themselves only a small proportion of cases can be saved. As with other antitoxins, there is no evidence that the antitetanic serum has any detrimental effect on the bacilli. It only neutralises the effects of the toxin. The standardisation of the antitetanic serum is of the highest importance. Behring recommended that for protecting animals a serum should be obtained of which one gramme will protect 1,000,000 grms. weight of mice against the minimum fatal dose of the bacillus or toxin. A mouse weighing twenty grms. would thus require ·00002 grm. of the serum to protect it against the minimum lethal dose. In the injection of such a serum subsequent to infection, if symptoms have begun to appear, 1000 times this dose would be necessary; a few hours later 10,000 times, and so on.

The Therapeutic Application of Tetanus Antitoxin.—As the results of his experiments, Behring aimed at obtaining a curative effect in the natural disease occurring in man. For this purpose he immunised large animals such as the horse, the sheep, and the goat. It is found that the greater the degree of the natural susceptibility of an animal to tetanus, the easier is it to obtain a serum of a high antitetanic potency. The horse is,

therefore, the most suitable animal and is usually employed. The serum is now standardised by a method similar to that set up for diphtheria antitoxin (see Chapter XXII.), and its strength is reckoned in terms of similar units. In this country the unit ordinarily used is that determined by the method practised in the U.S.A., and the sera contain from 150 to 800 units per c.c. Sera maintain their potency for a considerable period, but a serum more than a year old should not be used unless it has been subjected to fresh standardisation. Sera should always be stored in a dark and cool place.

The essential factors for the success of serum therapy are, first, that there should not be an hour of unnecessary delay in commencing treatment after a case is seen, and secondly, that the antitoxin should be given in proper amount. There are four paths by which the serum may be given, namely, subcutaneously, intramuscularly, intravenously, and intrathecally by lumbar puncture. The disadvantage of the first two methods is that absorption is relatively slow—of the latter, that elimination is relatively rapid. The earlier injections ought therefore to be given either intravenously or intrathecally, and some difference of opinion exists as to the relative merits of the two routes. The chief advantage of the former is that large quantities of the remedial agent can be quickly administered, and Henderson Smith has shown that a high concentration of antitoxin in the body fluids is maintained for a considerable time; the neutralisation of toxin passing out from a focus of infection is thus facilitated. The argument in favour of the intrathecal method is that the serum thereby gains rapid access to the grey matter of the cord on which the toxin is exerting its specific action. In the absence of definite experimental evidence, the effects of treatment by the two methods can only be judged of by the clinical results and, up to the present, data for a final decision are not available. The War Office Committee officially recommends that the first injections should be given by the intrathecal method and the later by intramuscular and subcutaneous routes, the principle being that, as the antitoxin first given is eliminated, its place is taken by the more slowly absorbed and therefore more gradually eliminated moieties.

For the earlier injections—intrathecal or intravenous—the patient must be put under a general anæsthetic. The intrathecal injection is practised by making an ordinary lumbar puncture and withdrawing 20 c.c. of cerebro-spinal fluid. A corresponding amount of antitoxin, warmed to the body temperature, is then slowly introduced, the pulse and respiration being

carefully watched. Similar precautions are observed with the intravenous method. In an acute case from 50,000 to 100,000 units should be administered during the first few days; if the symptoms are specially severe a high titre serum should be used. Bruce gives the following scheme of treatment as suitable:—

	Subcutaneous.	Intramuscular.	Intrathecal.
1st day		8000 units	16,000 units
2nd day		8000 units	16,000 units
3rd day		4000 units	8000 units
4th day		4000 units	8000 units
5th day	2000 units		
7th day	2000 units		
9th day	2000 units		

In giving a prognosis as to the probable result, the two clinical observations on which chief reliance ought to be placed are the presence or absence of interference with respiration, and the rapidity with which the groups of muscles usually affected are progressively attacked. If dyspnœa, or irregularity in respiration, or rise in temperature comes on soon, and if group after group of muscles is quickly involved, then the outlook is extremely grave. The advent of laryngeal spasm may necessitate the performance of tracheotomy or the practice of artificial respiration. Further, the shorter the time between the infliction of the wound and the appearance of symptoms the graver is the outlook.

The results of the therapeutic use of antitoxin in tetanus have not been so good as in the corresponding case of diphtheria, and it is doubtful whether the course of a rapid intoxication can be in any way, or by any means, modified. The great difficulty is that an infection is not suspected till the tetanus bacilli have already begun to manifest their gravest effects. This is in contrast with diphtheria, where the multiplication of the bacilli early originates a well-marked local clinical feature—sore throat—which draws attention to the possibility of their presence and enables the intoxication to be anticipated. Still, in tetanus, antitoxin treatment should always be undertaken, as it is impossible to say that thereby the course of a subacute infection may not be deflected from a fatal to a non-fatal issue.

The Prophylactic Use of Tetanus Antitoxin.—The advisability of giving antitoxin prophylactically in every case of a ragged, unhealthy-looking wound, especially when contaminated with soil, has been advocated. The principle has, for a considerable time, been applied in connection with the injuries contracted

during the Independence Day celebrations in America, and of which tetanus is a not uncommon sequel; a very definite fall in the death-rate has been thereby effected. It is during the present war, however, that the success of prophylaxis has been established. During the early months, in the fighting on the Marne and the Aisne, tetanus was rife—its incidence in the wounded brought to Britain being about sixteen per thousand. Since the autumn of 1914 prophylactic injections of antitoxin have been given to every wounded man—as a rule at the dressing-stations—with the result that the corresponding incidence has been reduced to two per thousand. The initial dose is 500 units administered subcutaneously, and, as passive immunity is of relatively short duration, this dose should be repeated at seven-day intervals till four doses have been given. Further, when at later periods operative interference, even with healed wounds, is necessary, a similar dose should be given, either subcutaneously forty-eight hours, or intramuscularly twelve hours, previous to the operation.

Attention has already been directed to the effects of the prophylactic use of antitoxin in modifying the clinical type of the disease.

Methods of Examination in a case of Tetanus.—The routine bacteriological procedure in a case presenting the clinical features of tetanus ought to be as follows:

(*a*) *Microscopic.*—Though tetanus is not a disease in which the discovery of the bacilli is easy, still microscopic examination should be undertaken in every case. From every wound or abrasion from which sufficient discharge can be obtained, film preparations ought to be made and stained with any of the ordinary combinations, *e.g.*, carbol-fuchsin diluted with five parts of water. Drumstick-shaped spore-bearing bacilli are to be looked for. The presence of such, having characters corresponding to those of the tetanus bacilli, though not absolutely conclusive proof of identification, is yet sufficient for all practical purposes. If only bacilli without spores resembling the tetanus bacilli are seen, then the identification can only be provisional.

The microscopic examination of wounds contaminated by soil, etc., may in some cases lead to the anticipation that tetanus will probably result.

(*b*) *Cultivation.*—The methods to be employed in isolating the tetanus bacilli have already been described (p. 422). It may be added, however, that if the characteristic forms are not seen on microscopic examination of the material from the wound, they may often be found by inoculating a deep tube of one of the glucose media with such material, and incubating for forty-eight hours at 37° C. At the end of this period, spore-bearing tetanus bacilli may be detected microscopically, though of course mixed with other organisms.

(*c*) *Inoculation.*—Mice and guinea-pigs are the most suitable animals. Inoculation with the material from a wound should be made subcutaneously. A loopful of the discharge introduced at the root of the tail

in a mouse will soon give rise to the characteristic symptoms, if tetanus bacilli are present. With suspicious organisms isolated by culture it is well to use the splinter method (p. 428), as some strains of the b. tetani tend to produce little toxin in artificial media, and may be injected without causing tetanic symptoms.

Bacillus Botulinus.

The term "meat-poisoning" embraces a number of conditions produced by different agents, and the bacilli related to one class of case have already been discussed (p. 380). Another group was shown by van Ermengem in 1896 to be caused by an anaerobic bacillus to which he gave the name *bacillus botulinus*. He cultivated the organism from a sample of ham, the ingestion of which in the raw condition had produced a number of cases of poisoning, some of them followed by fatal result. The symptoms in these cases closely corresponded with those occurring in the so-called "sausage poisoning." Such cases form a fairly well-defined group, the symptoms in which are chiefly referable to an action on the medulla, and, as will be detailed below, similar symptoms have been experimentally produced by means of the bacillus mentioned or its toxins. The chief symptoms of this variety of botulismus, as detailed by van Ermengem, are disordered secretion in the mouth and nose, more or less marked ophthalmoplegia, externa and interna (dilated pupil, ptosis, etc.), dysphagia, and sometimes aphagia with aphonia, marked constipation and retention of urine, and in fatal cases interference with the cardiac and respiratory centres. Along with these there is practically no fever and no interference with the intellectual faculties. The symptoms commence at earliest twelve to twenty-four hours after ingestion of the poison. From the ham in question, which was not decomposed in the ordinary sense, van Ermengem obtained numerous colonies of this bacillus, the leading characters of which are given below. It may be added that Römer obtained practically the same results as van Ermengem in a similar condition, and that the bacillus botulinus has been cultivated by Kempner from the intestine of the pig. In the summer of 1918 cases of botulismus were said to have occurred in Great Britain. So far as we are aware, however, the b. botulinus was never isolated. (See Appendix, Acute Poliomyelitis.)

Microscopical and Cultural Characters.—The organism is a bacillus of considerable size, measuring 4 to 9 μ in length and ·9 to 1·2 μ in thickness; it has somewhat rounded ends and sometimes is seen in a spindle form. It is often arranged in

pairs, sometimes in short threads. Under certain conditions it forms spores which are oval in shape, usually terminal in position, and only a little thicker than the bacilli. It is a motile organism, and has 4 to 8 lateral flagella of wavy form. It stains readily with the ordinary dyes, and also retains the colour in Gram's method, though care must be employed in decolorising.

The organisms can be readily cultivated on the ordinary media, but only under strictly anaerobic conditions. In glucose gelatin a whitish line of growth forms with lateral offshoots, but liquefaction with abundant gas formation soon occurs. In gelatin plates the colonies after four to six days are somewhat characteristic; they appear to the naked eye as small semi-transparent spheres, and these on examination under a low power of the microscope have a yellowish-brown colour and are seen to be composed of granules which show a streaming movement, especially at the periphery. Cultures in glucose agar resemble those of certain other anaerobes; there is abundant development of gas, and the medium is split up in various directions. The cultures have a rancid, though not foul, odour, due chiefly to the development of butyric acid. It does not liquefy coagulated serum and M'Intosh places it in the non-proteolytic group. He finds that it ferments glucose, with evolution of gas, and, to a less extent, maltose, lactose, glycerine, and starch. The optimum temperature is below that of the body, namely, between 20° and 30° C.; at the body temperature growth is slower and less abundant and spore formation does not occur.

Pathogenic Effects.—Like the tetanus bacillus, the bacillus botulinus has little power of flourishing in the tissues, whereas it produces a very powerful toxin. Van Ermengem found that the characteristic symptoms could be produced in certain animals by administering watery extracts of the infected ham or cultures either by the alimentary canal or by subcutaneous injection. Here also there is a period of incubation of not less than six to twelve hours before the symptoms appear, and when the dose is small a somewhat chronic condition may result, in which local paralyses form a striking feature. The characteristic effects can also be produced by means of the filtered toxin by either of the methods mentioned, though in the case of administration by the alimentary canal the dose requires to be larger. As in the case of the tetanus poison, the potency of the toxin is remarkable, the fatal dose for a guinea-pig of 250 grm. weight being in some instances ·0005 c.c. of the filtered toxin. In cases of poisoning in the human subject, the effects would accordingly appear to be produced by absorption of the toxin from the

alimentary canal; it is only after or immediately before death that a few bacilli may enter the tissues. Van Ermengem obtained a few colonies from the spleen of a patient who had died from ham-poisoning. The properties of the botulinus toxin have been investigated, and have been found to correspond closely, as regards relative instability, conditions of precipitation, combination with sensitive cells (*i.e.*, of brain and cord), etc., with the toxins of diphtheria and tetanus. An antitoxin was prepared by Kempner by the usual methods, and was shown not only to have a neutralising property, but to have considerable therapeutical value when administered some hours after the toxin. The subject was studied by Leuchs, and he found that the combination toxin-antitoxin can be split up by the action of acids and the two components recovered, just as Morgenroth showed to occur in the case of diphtheria (p. 565). The direct combining affinity of the toxin for the central nervous system was demonstrated by Kempner and Schepilewsky by the same methods as Wassermann and Takaki employed in the case of the tetanus toxin. The condition of the nerve cells in experimental poisoning with the botulinus toxin has been investigated independently by Marinesco and by Kempner and Pollack, and these observers agree as to the occurrence of marked degenerative changes, especially in the motor cells in the spinal cord and medulla. Marinesco also observed hypertrophy and proliferation of the neuroglia cells around them.

These observations, therefore, show that in one variety of meat-poisoning the symptoms are produced by the absorption of the toxins of the bacillus botulinus from the alimentary canal, and, as van Ermengem points out, it is of special importance to note that the meat may be extensively contaminated with this bacillus, and may contain relatively large quantities of its toxins without the ordinary signs of decomposition being present. The production of an extracellular toxin by this organism, with extremely potent action on the nervous system, is a fact of great scientific interest, and has a bearing on the etiology of other obscure nervous affections.

Anaerobes in Infected Wounds.

It may be said that practically all such anaerobes come from the soil and that their original source is chiefly animal fæces. All cultivated soils are accordingly rich in such organisms. In the case of lacerated wounds contaminated by soil, and especially in gunshot wounds, we have thus two main factors, the presence of

damaged or necrosed tissues, and infection by various anaerobes of intestinal origin, though there are also some aerobes present from the same and other sources. At an early stage the number and variety of organisms, many of them spore-bearing, form a very striking feature. As reactive processes, exudation, leucocyte, emigration, etc., come into play, we find in favourable cases that the anaerobes gradually diminish, while the aerobes continue to flourish, though in deep clefts and in necrosed tissue the former may persist for a long time. This change in the flora becomes more marked as suppuration becomes established and progresses; the ordinary pyococci, apparently derived from the skin, appear and multiply at the expense of the various bacilli, enterococci, etc., till ultimately they are practically the only organisms present. So far as serious complications are concerned, we may say that in the early stages these are chiefly due to the anaerobes and in the later stages to streptococci and, to a less degree, to staphylococci. We have here to deal with the anaerobes, and these have the following effects: (*a*) poisoning by toxins, the outstanding example being of course the b. tetani; (*b*) invasion of the tissues, the production of spreading œdema, necrosis, and gaseous emphysema—generally comprised under the term "gas gangrene"; and (*c*) merely local inflammatory and putrefactive changes. The b. tetani has already been treated of, and it has been shown that it has no more infective or invasive properties than other saprophytic anaerobes. The number of anaerobes separated from war wounds is large, and with regard to them two general statements may be made. In the first place, only a few have been shown to cause by themselves definite spreading infections. Of these it is generally accepted that the b. welchii is by far the most important, next comes the *vibrion septique*, and then probably the b. œdematiens. In the second place, the organisms which sometimes cause these serious results are commonly present in wounds from which no complications arise. There must accordingly be favouring conditions in certain cases which lead to these grave and often fatal results. This of course holds with regard to bacterial infections in general, but it is especially well exemplified in the lesions in question. The b. welchii, for example, is commonly present in putrid wounds—in the great majority of cases it leads to no harm, yet in a certain small proportion it causes one of the most rapidly fatal infections known. As possible determining influences, we might mention the degree of the injury, the dose of infection, possibly the virulence of the invading organism, and the adjuvant effect of other organisms. In the case of gas gangrene

produced by the b. welchii, infection of lacerated muscle has been shown to be an extremely important factor in its origin and spread (*vide infra*).

This group of organisms may be said to have the following characters. They are, on the whole, fairly large bacilli, easily stained and Gram-positive, though the occurrence of Gram-negative forms is fairly common in older cultures. Spore-formation is the rule; the spores, which are rounded or oval, have a thickness exceeding that of the bacillus, sometimes markedly so, and may be terminal, subterminal, or central in position. In a given species the position of the spore may vary somewhat, but in the case of some, *e.g.*, the b. tetani, the spore is always terminal. The majority possess numerous lateral flagella, and many are actively motile; a few, *e.g.*, the b. welchii, are non-motile. The earlier means of differentiation depended on morphological and cultural features in a few media, and on pathogenic effects. All these factors, however, vary somewhat. More recently the physical and chemical changes produced in various definite media have been added as a means of distinguishing them. The important work of M. Robertson, Henry, Wolf and Harris, and M'Intosh may be mentioned in this connection, and to their publications we are indebted for many of the facts stated below. The appearances of superficial and deep colonies have also been found of service. The result of biological inquiries has been to divide the organisms according to their metabolic activities into two main groups, namely, (1) the *saccharolytic* or *non-proteolytic* and (2) the *proteolytic*. This distinction must be taken in a broad sense, as the proteolytic members have an action on some sugars. Variations are met with in the rapidity of the fermentation and also in the products which are ultimately formed. The recognition of these two main groups is of importance also from the pathological point of view, as the chief organisms which produce spreading lesions belong to the saccharolytic group. In fact there is often a "saccharolytic stage" of advancing infection, followed by a "proteolytic stage" of putrefaction. We shall give the chief characters of the most fully studied of these organisms, dealing first with the non-proteolytic, which are the most important.

Bacillus Welchii (B. Aerogenes Encapsulatus).

This bacillus was first described by Welch and Nuttall in 1892, who showed that it was the cause of the extensive gaseous development which sometimes occurs in the organs *post mortem*,

resulting in the formation of rounded gas cavities. It is now recognised that it is identical with an organism cultivated later by E. Fraenkel and called by him the *bacillus phlegmones emphysematosæ*. The same bacillus was described by Veillon and Zuber, who gave it the name *bacillus perfringens*, by which name the organism, for some reason, is now generally known. During the war it has come into great prominence, as it has been proved to be by far the most important agent in the production of gas gangrene. We shall speak of it as the b. welchii.

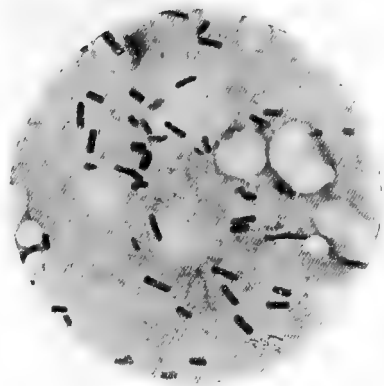

FIG. 125.—Film taken from margin of spreading gas gangrene, showing numerous examples of b. welchii (pure).[1] Gram's stain. ×1000.

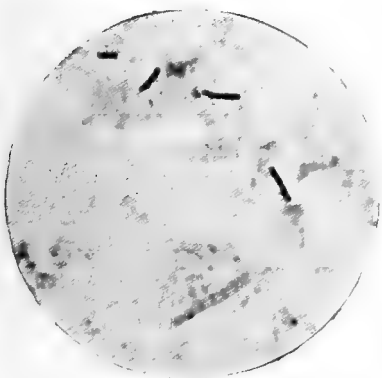

FIG. 126.—Film from necrosed muscle in gas gangrene, showing a few b. welchii with remains of muscle fibres. Gram's stain. ×1000.

Microscopical Characters. — As seen in the serous fluid in a case of spreading gas gangrene, it is a comparatively large bacillus, measuring usually 4–6 μ in length (Figs. 125, 126) and relatively stout; but the thickness varies somewhat. Its ends are somewhat rounded, though those of some of the shorter forms are almost square. In cultures it is rather pleomorphous and in sugar-free media there is a tendency to form filaments (Henry); again, short, almost coccus-like forms, may be met with. It is

[1] We are indebted to Major J. W. M'Nee, R.A.M.C., for the preparations from which Figs. 125, 126, 127, and 132 were made.

readily stained with the basic dyes, and is Gram-positive, though in older cultures Gram-negative forms occur. In the tissue fluids it usually has a distinct and fairly broad capsule, hence the original name; sometimes, however, no capsule is seen; the presence or absence of the capsule depends on conditions already referred to (p. 228). In ordinary media, again, no capsule is seen, but in serum media it can be demonstrated by special methods (*cf.* pneumococcus). The organism is non-motile, and no flagella have been demonstrated.

In the spreading area of the disease no spores are found, though they have been described in the later stages when the bacillus is associated with other organisms. At first it was believed not to form spores, but, as was first shown by Dunham, spores are produced in serum media; they are oval and fairly large, usually subterminal, occasionally central. In ordinary media, however, and in the presence of a trace of sugar, no spores are formed.

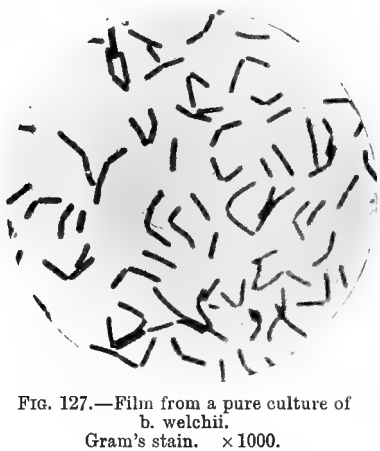

FIG. 127.—Film from a pure culture of b. welchii. Gram's stain. ×1000.

Cultivation.—The bacillus welchii can be readily grown on various media, but only under strict anaerobic conditions. It flourishes best at the temperature of the body, but grows also at room temperature. On serum agar the superficial colonies are circular in form, moist in appearance, with smooth margins, there being no radiate outgrowth or downgrowth; the deep colonies are usually oval or lenticular in form, with sharp outline. It produces no liquefaction either in gelatine or in solidified serum. In milk the characters of the growth are of importance. It grows rapidly and leads to production of coagulation of the medium, the clot becomes broken up by gas bubbles—the so-called "stormy reaction"—and ultimately comes to form irregular tough masses bathed in comparatively clear whey. There is no digestion of the casein even after a long time. The culture has an odour of butyric acid. These

effects in milk are practically the same as those described by Klein in the case of his bacillus enteritidis sporogenes, and the two organisms concerned in them are probably the same, though it is now generally held that Klein's cultures were impure, the b. sporogenes (*vide infra*) or some allied putrefactive organism also being present. In cooked meat medium the b. welchii produces a pink colour with considerable amount of gas; there is a sour smell, but no putrid odour or blackening of the medium. The organism may be said generally to be an active fermenter of sugars and some other substances, though strains differ somewhat in this respect. It produces acid and gas from glucose, maltose, lactose, saccharose, and starch, and also from glycerine; inulin is sometimes fermented, sometimes not. Fermentation of these substances takes place with great rapidity, but the acid formed has a markedly deterrent action on the growth, and soon leads to its cessation. The b. welchii has thus very active saccharolytic action, whereas its digestive effect on proteins is almost nil, and these properties will be found to have an important bearing on its pathogenic effects.

FIG. 128.—Bacillus welchii, showing capsules; film preparation from bone-marrow in a case where gas cavities were present in the organs. ×1000.

Pathogenic Effects.—In addition to invading the blood stream about the time of death, and giving rise to gas cavities in the organs, the bacillus welchii has been found in various emphysematous and gangrenous conditions in civil life, the infection usually starting in connection with the alimentary canal. It is also, as has been indicated, by far the most important cause of gas gangrene from war wounds. In this affection it is now recognised that the starting-point is usually some laceration of muscle, which has become contaminated with soil containing the bacillus. The spread of the disease is often remarkable, as cases have been recorded in which extensive emphysematous swelling with gangrene of a limb has occurred with a fatal result, well

within twenty-four hours. In some cases the affection may be confined to individual muscles, and resection of these has been carried out, sometimes with success. Within a muscle, the necrotic change may spread along individual fibres with great rapidity, leaving others in relation to them unaffected. The stages as described by M'Nee and Shaw Dunn are as follows. The bacilli spread with great rapidity along the interstitial tissue of the muscle, and may be found beyond the actual site of gangrene. They are present often in very large numbers and in practically pure culture. The fibres thus surrounded become somewhat swollen, altered in staining reaction, and separated from the interstitial tissue by a zone of serous fluid, poor in protein. The fibres then become completely necrosed, the sarcolemma nuclei losing their staining reaction, and about this time the fluid within the sarcolemma comes to contain the bacilli in large numbers. There is then evolution of gas, and the muscle substance becomes broken up and disintegrated, though the transverse striation may persist for a considerable time (Fig. 126). Finally the dead muscle may become invaded by other organisms, and become putrid and softened. Along with these changes in the muscle there occur œdema and emphysema in the interstitial and subcutaneous connective tissue, while the skin shows various kinds of discoloration, and the affected part is swollen, tense, and gives crackling on palpation.

To the naked eye the affected muscle is at first swollen and pale and has lost its elasticity; it soon assumes a brownish-red colour, is beset with gas bubbles and is putty-like in consistence, while later it becomes brownish yellow, greenish, or dark red. It must be noted, however, that the bacillus does not cause the ordinary changes of putrefaction.

The essential feature is thus seen to be the extraordinary extent and rapidity of the growth of the bacilli, which is attended by evolution of gas, chiefly from the muscle carbohydrates, and associated necrosis of muscle. Wright has found that locally there is a fall in the anti-tryptic action of the serum along with increased acidity, and he considers that the co-existence of these factors favours the growth of the bacilli and leads to their rapid spread. He also finds that in grave cases there is a fall in the alkalinity of the blood—an acidæmia. The spread of the bacilli is also attended by marked œdema, but with practically no leucocyte reaction, unless when the spread is becoming arrested or when it takes place around other organisms. The growth of the bacilli is essentially local, but they may enter the blood shortly before death, when they have been found

in a certain proportion of cases. Instances have also been recorded in which they have settled in other parts of the body and produced lesions there—the so-called metastatic gas gangrene.

Experimental Inoculation.—The virulence of the b. welchii varies considerably. Some strains when injected into a guinea-pig, even in considerable doses, cause only some inflammatory swelling which passes off; especially is this the case when an emulsion of the bacilli from a surface culture is used. Other strains, again, produce a fatal result, even in small doses; there occurs at the site of injection an inflammatory œdema with blood-stained fluid and some evolution of gas, and a certain amount of necrosis of the underlying muscle. Bacilli are abundant locally, but only a few are present in the blood stream. When the dose is sublethal a local gangrene may occur, with subsequent separation of the dead tissue; thereafter healing may rapidly follow. Intramuscular injection is the most effective method, especially in the rabbit, which is more resistant than the guinea-pig. The pigeon is found to be the most susceptible of the animals hitherto tested, the lethal dose being only a fraction of that for the guinea-pig. Injection into the pectoral muscle of a pigeon causes lesions in the muscle closely resembling those in gas gangrene in man, and death follows very rapidly, sometimes within a few hours. Most observers have found filtered cultures to be practically non-toxic, but recently Bull and Pritchett have succeeded in obtaining a true exotoxin. The medium used by them was plain meat bouillon containing fragments of sterile skeletal muscle of the pigeon or rabbit. After inoculation the medium is incubated under anaerobic conditions at 37° C. for twenty-four hours, and is then filtered through a Berkefeld N candle. The filtrate was found to be highly toxic for all the animals mentioned above, and gave rise to local lesions closely resembling those caused by the bacilli themselves. In addition to having a local necrotic effect on muscle, the toxin, or a moiety of it, is actively hæmolytic, and leads to a massive destruction of red corpuscles when injected intravenously. Bull and Pritchett believe, accordingly, that death from gas gangrene is due to a true toxæmia and not to the production of acid in the tissues as has been supposed by some. By means of injecting carefully graduated doses of the toxin, they have produced an active immunity, and the serum of the treated animals possesses anti-toxic properties. The antitoxin neutralises all the effects of the toxin in multiple proportions, and is protective and curative against infection with the bacillus in the pigeon. The applica-

tion of antitoxic serum to the treatment of the human disease will be looked forward to with interest.

Bacillus fallax.—This organism was separated by Weinberg and Seguin, and the name was given by them on account of its resembling the b. welchii. It is smaller than the latter organism, being both somewhat thinner and shorter. It is Gram-positive, and in cultures forms spores which are usually subterminal in position. It possesses lateral flagella and is feebly motile. The growths resemble those of b. welchii, but the young surface colonies are more transparent and the older ones have a more irregular margin. The action on milk is much less marked, the formation of clot and gas usually occurring only after several days; the action on sugars also is feebler and more restricted. It has no digestive effect on casein or on coagulated serum. It thus may be described as a non-proteolytic bacillus with somewhat weak saccharolytic action. Recent cultures produce a gelatinous œdema on injection into a guinea-pig; they, however, soon lose their virulence.

Vibrion Septique (Pasteur), Bacillus of Malignant Œdema (Koch).

This organism was first discovered by Pasteur in putrefying carcases. He described its characters, distinguishing it from the anthrax bacillus, which it somewhat resembles morphologically, and also the lesions produced by it. He found that it grew only in anaerobic conditions, but was able to cultivate it merely in an impure state. A similar organism was later more fully studied by Koch, which he considered to be the same as Pasteur's *vibrion septique*. He pointed out, however, that the disease produced by it is not really a septicæmia, as immediately after death the blood may be free from the bacilli. Accordingly he gave to it the name bacillus of malignant œdema, from its pathogenic effects in animals. There has, however, been a considerable amount of confusion as to the essential features of these organisms, the original descriptions being naturally incomplete, and some observers have described under the term bacillus of malignant œdema certain non-pathogenic anaerobes which produce merely putrefactive changes.

In pre-war times "malignant œdema" in the human subject was usually described as a spreading inflammatory œdema attended with emphysema, and ultimately followed by a certain amount of gangrene. In only some cases of this nature, however, the bacillus of malignant œdema is present, and it is usually associated with other organisms which aid its spread. One of us, however, observed a fatal case in which the bacillus was present in pure condition. Here there occurred intense œdema with swelling and induration of the tissues, and the

formation of vesicles on the skin. These changes were attended with a reddish discoloration, afterwards becoming livid. Emphysema was not recognisable until the very tense limb was incised, when it was detected, though in small degree. Further, the tissues had a peculiar heavy, but not putrid, odour. The bacillus, which was obtained in pure culture, was present in enormous numbers in the affected tissues, attended by cellular

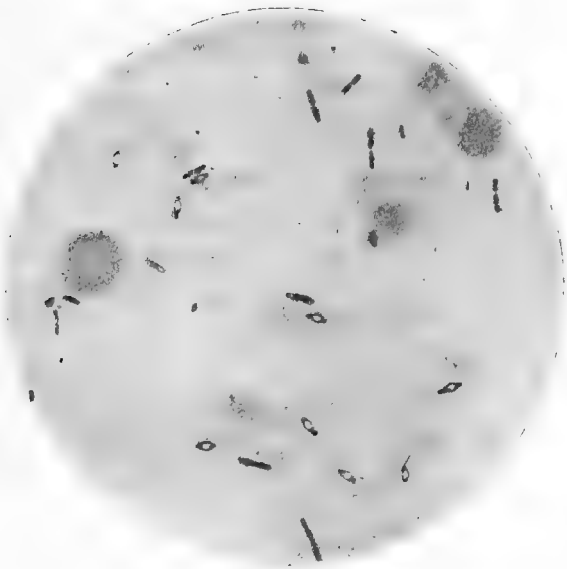

FIG. 129.—Film preparation from the affected tissues in a case of malignant œdema in the human subject, showing the spore-bearing bacilli.

Gentian-violet. ×1000.

necrosis and serous exudation. The picture, in short, corresponded with that seen on inoculating a guinea-pig with a pure culture. The term "malignant œdema" should be limited in its application to cases in which the bacillus in question is present. In most of these there is a mixed infection; in some the bacillus may be present alone.

During the war the organism has been found in putrid wounds and cases of gas gangrene. M'Intosh, in fact, found it to be next in order of frequency to the b. welchii in gangrenous

wounds. Weinberg places it along with the latter organism as a cause of "classical gas gangrene," though it is much less common, and usually occurs in association with other organisms. He, moreover, states that cases of pure infection are rare, and that in these emphysema is not a striking feature, gas occurring only in the deeper tissues in small bubbles, and sometimes only recognisable at operation. These features accordingly correspond with those in the case referred to.

Microscopical Characters.—The *vibrion septique*, or bacillus of malignant œdema, is a comparatively large organism, being slightly less than 1 μ in thickness, that is, thinner than the anthrax bacillus. It usually occurs in the form of single rods 3 to 10 μ in length, but both in the tissues and in cultures in fluids it frequently grows out into long filaments, which may be uniform throughout or segmented at irregular intervals. In cultures on solid media it chiefly occurs in the form of shorter rods with somewhat rounded ends. The rods are motile, possessing several laterally placed flagella. Motility is usually well marked in the serous exudate of the lesions, but in cultures only a few bacilli may show active movement. Under suitable conditions they form spores, which have an oval shape, their thickness somewhat exceeding that of the bacillus; they are central or subterminal in position. In acute spreading lesions the bacilli are usually free from spores, but at a later period they may be found (Fig. 129). The bacillus can be readily stained by any of the basic aniline stains. There is difference of statement as to the reaction to Gram's stain. Earlier writers agreed that the organism was Gram-negative, but in most recent papers it is described as Gram-positive, though it is admitted that in older cultures Gram-negative forms appear.

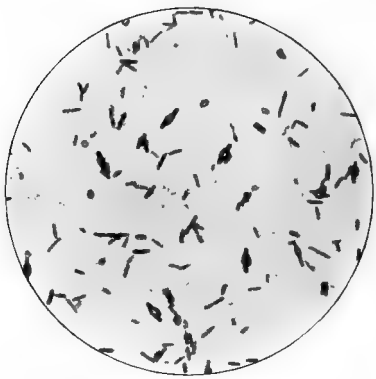

FIG. 130.—Bacillus of malignant œdema, showing spores. From a culture in glucose agar, incubated for three days at 37° C.
Stained with weak carbol-fuchsin. ×1000.

Characters of Cultures.—This organism is a strict anaerobe;

it grows readily at the room temperature, but the optimum is the temperature of the body.

In deep tubes of glucose agar at 37° C. growth is extremely rapid. Along the line of puncture, growth appears as a somewhat broad whitish line, with short lateral projections here and there (Fig. 131, B). Gas may be formed, but this is most

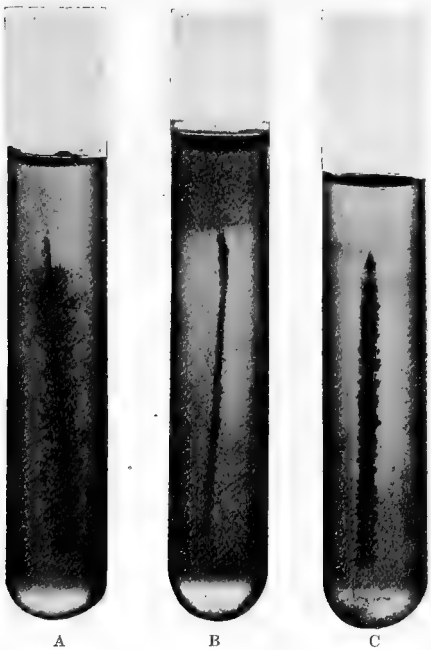

FIG. 131.—Stab cultures in agar, five days' growth at 37° C. Natural size.

A. Tetanus bacillus. B. Bacillus of malignant œdema. C. Bacillus of quarter-evil (Rauschbrand).

marked in a shake culture. The individual deep colonies are woolly in appearance without definite centre, whilst the superficial ones are thin discs with irregular peripheral radiations. The growths generally are like those of the b. tetani, but have a somewhat coarser character. Cultures in gelatin present somewhat similar features, and the deep colonies have been compared to those of the b. subtilis; liquefaction of the medium

follows. The cultures possess a peculiar heavy, though not putrid, odour. M'Intosh finds that the organism ferments glucose, maltose, and lactose, but not saccharose, inulin, glycerin, or starch. His strains produced coagulation of milk, but without any digestion of the casein, and caused no liquefaction of coagulated serum; in cooked meat medium there was no change in colour. He accordingly places the organism in the non-proteolytic group. Strains described by other observers, however, both liquefy coagulated serum and digest milk. It is manifest that further definition of the organism is necessary. Spore formation occurs in cultures above 20° C., and is usually well seen within forty-eight hours at 37°C.

Experimental Inoculation. — A considerable number of animals — the guinea-pig, rabbit, dog, sheep, and goat, for example—are susceptible to inoculation with this organism. There is general agreement as to its marked pathogenic properties. Especially is this the case when the serous exudate containing the bacillus is used for inoculation, a mere fraction of a cubic centimetre being a fatal dose. M'Intosh found that with his strains ·01 c.c. of a fluid culture injected intramuscularly killed a guinea-pig within twenty-four hours.

Subcutaneous inoculation with pure cultures produces in the guinea-pig chiefly a widespread gelatinous œdema, and a blood-stained serous fluid exudes from the affected part. The underlying muscles are softened and partly necrosed, and of bright red colour; but there is little formation of gas, and putrid odour is almost absent. The internal organs show little change. The bacilli are present in the peritoneal fluid, and occur as long motile filaments. They have sometimes been cultivated from the blood, but they are always scanty. Infection with the organism is said to occur frequently when a little garden-earth is introduced subcutaneously in the guinea-pig, but in this case the local lesion presents a putrid character, owing to the presence of other organisms.

When the bacilli are injected into mice, however, they enter and multiply in the blood stream, and they are found in considerable numbers in the various organs, so that a condition not unlike that of anthrax is found. The spleen also is much swollen.

Immunity.—Malignant œdema was one of the first diseases against which immunity was produced by injections of toxins. The filtered cultures of the bacillus in sufficient doses produce death with the same symptoms as those caused by the living organisms, but a relatively large quantity is necessary. Chamberland and Roux (1887) found that if guinea-pigs were injected

with several non-fatal doses of cultures sterilised by heat or freed from the bacilli by filtration, immunity against the living organism could be developed in a comparatively short time. They found that the filtered serum of animals dead of the disease is more highly toxic, and also gives immunity when injected in small doses. These experiments were confirmed by Sanfelice.

Bacillus Œdematiens.

This organism, first described by Weinberg and Seguin, has the following characters. It is a fairly large bacillus, of about the same size as the b. welchii, but tending to be rather longer. It is distinctly pleomorphous, often occurring in C and S forms, and growing also in chains. It is Gram-positive, but Gram-negative forms are found in older cultures. It possesses numerous lateral flagella, though in ordinary conditions motility is practically absent. Spore-formation occurs, the spores being usually subterminal in position.

Cultivation.—The organism grows well on all the ordinary media down to a temperature of about 20° C., but only under strict anaerobic conditions. On solid media the deep colonies are small, somewhat irregular balls with woolly margin, while the superficial ones are film-like with wavy border. In glucose-bouillon there is produced at first a general turbidity, but this soon clears off, leaving only a slight deposit at the bottom of the tube; this is due to the rapid disintegration of the bacilli, the deposit being formed chiefly of spores. In milk it causes the formation of a loose acid clot, which falls to the bottom as a grumous deposit; there is no digestion of the casein, nor is there any liquefaction of gelatine or digestion of coagulated serum. It actively ferments nearly all the ordinarily used sugars with evolution of gas.

In cooked meat medium it produces a pink colour, which afterwards fades almost to a white, and there is slight formation of gas. The bacillus may thus be regarded as belonging to the saccharolytic type of anaerobes.

Pathogenic Effects.—In a series of cases of gas gangrene Weinberg found the b. œdematiens to occur next in order of frequency to the b. welchii, and he considers it to be the most important agent in what he calls the "toxic form" of gas gangrene. This type is characterised by a rapidly spreading gelatinous œdema, with little or no gas formation, and by severe symptoms of general poisoning. Blood culture usually gives a negative result, though the bacillus may be found in the

blood after death. Intramuscular or subcutaneous injection in the guinea-pig gives a similar picture, the chief feature being the extent and thickness of the œdema; the lesion has no putrid odour. The organism has been shown by Weinberg to form a soluble toxin, which in the case of some strains is very active. Injection of a filtrate from a fluid culture reproduces the characteristic œdema in the guinea-pig. He has also produced an antitoxin which is efficient when tested experimentally, and which has been used in some cases of the human infection, apparently with success.

Bacillus tertius.—This is another saccharolytic bacillus, but with *terminal spores.* It is common in contaminated wounds, and the name was given by Henry, as he found it to be third in order of frequency among the anaerobes. It is regarded as being probably the same as the bacillus IX of von Hibler and the bacillus Y of Fleming. The b. tertius is a fairly long and thin bacillus, and is often somewhat curved; it is Gram-positive, but the power of retaining the stain is soon lost in cultures. It is feebly motile or non-motile. The spores are terminal; the small forms are round, and stain deeply with a basic dye; the larger are oval, racquet-shaped, sometimes of considerable length, and give the ordinary staining reactions of spores. Occasionally a spore is present at either end of a bacillus. The superficial colonies are round, semi-transparent discs, which do not become large; the deep colonies are of lenticular shape; occasionally, from both, small offshoots occur. On a moist surface there is a tendency for the growth to spread as a thin film. In milk a small amount of gas is produced, and a day or two later a soft friable coagulum. In cooked meat medium both acid and gas are formed; later the fluid becomes clear and the meat assumes a pink colour. There is no liquefaction of gelatine or coagulated serum. The organism has wide fermentative action when tested on various carbohydrates, but different strains vary in this respect. It has practically no pathogenic effects when tested experimentally, though it probably gives rise to gas-formation in wounds.

The three following organisms are examples of the proteolytic group:—

Bacillus sporogenes.—This organism, which was first separated from fæces by Metchnikoff and described by him, is probably the commonest anaerobe in cultivated soil. It is present in the great majority of putrid wounds, and owing to its rapid growth and spore formation, often interferes with the separation of other anaerobes. It is a fairly large bacillus, of about the same length as the b. welchii, but thinner, and usually occurs as single elements. It is Gram-positive, but as is common with members of the group, Gram-negative forms are to be found in older cultures. Spore-bearing forms are common in wounds, and in cultures spores are formed with great rapidity, so that they may be seen within twenty-four hours. The spores, which have very high powers of resistance, are usually subterminal, though occasionally central in position. The organism possesses numerous lateral flagella, and most strains are actively motile. It grows readily under anaerobic conditions, and the cultures have a markedly putrid odour. In deep glucose-agar tubes the growth forms a

thick line, from which there are short and stout lateral offshoots, attended by abundant gas formation, while individual colonies are small balls with woolly margin. Superficial colonies have a granular centre and present an arborescent appearance at the edge. The organism rapidly liquefies gelatine and coagulated serum, and also pieces of coagulated white of egg. In cooked meat medium there is evolution of gas and rapid digestion; the meat assumes a dirty, purplish tint, and ultimately becomes blackened. In milk there is a precipitation of casein without actual coagulation, and then digestion rapidly follows. The organism ferments glucose, lævulose, and maltose, but none of the other sugars ordinarily used. The organism is thus seen to have marked proteolytic properties, and it has been shown to form amino-acids, and as final products ammonia, sulphuretted hydrogen, and various volatile substances. It forms large quantities of butyric acid even in sugar-free media (Wolf and Harris).

The b. sporogenes has little or no pathogenic properties when injected in animals, a comparatively large amount of pure culture producing only a local swelling which passes off; and observations on gunshot wounds supply no evidence that it invades the healthy tissues. It may be regarded chiefly as a proteolytic saprophyte which grows on dead and dying tissues and brings about digestive softening and putrefactive changes. It thus readily invades the tissues already damaged by other organisms, *e.g.*, the b. welchii. There is also experimental evidence that its presence aids the pathogenic effects of other organisms. The b. sporogenes is closely allied to another anaerobe described under the name b. putrificus.

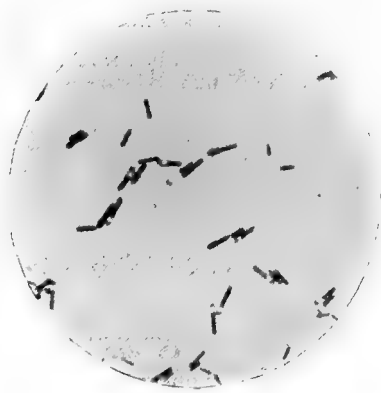

FIG. 132.—**B.** sporogenes, pure culture, showing sub-terminal spores. Stained with carbol-thionin blue. ×1000.

Bacillus histolyticus.—This is another proteolytic and putrefactive anaerobe separated by Weinberg from cases of gas gangrene. It is 2-6 μ in length and rather thinner than the b. welchii; it is often arranged in pairs. It is Gram-positive and forms large oval subterminal spores. The surface growth is in the form of a very thin film, with offshoots at the margin. Its action on milk and coagulated serum is similar to that of the b. sporogenes, but is even more rapid. In cooked meat medium also it produces very rapid digestion, with foul odour, and one feature described by Henry is the separation of white balls of acicular crystals which are probably tyrosin—an appearance which is probably characteristic of this organism. The cultures have a foul odour. A striking evidence of the proteolytic action of this organism is seen when it is injected subcutaneously in a guinea-pig. A rapid

digestion of the tissues in the vicinity occurs so as sometimes actually to expose the bones.

Bacillus putrificus.—This anaerobe was first described by Bienstock, who considered it the chief agent in putrefaction—hence the name. It measures usually 5–6 μ in length, though shorter and also longer filamentous forms are met with, and is relatively slender. It is actively motile and forms oval terminal spores which are large in proportion to the size of the rod. It grows readily under anaerobic conditions and gives a very foul odour in all media. The superficial colonies are transparent discs rounded or irregular in form, while the deep ones are woolly in appearance not unlike those of the b. sporogenes. The organism has marked proteolytic action, rapidly liquefying gelatine and coagulated serum, and the ultimate products are comparatively simple compounds, including various gases. Bienstock found that it did not ferment carbohydrates, but strains isolated by other workers have fermented certain of the sugars. To the sugar-fermenting variety Bienstock gave the name b. paraputrificus. Inoculation experiments with the b. putrificus show that it is practically devoid of pathogenic properties.

Quarter-evil (German, Rauschbrand; French, Charbon Symptomatique).

The characters of the bacillus need be only briefly described, as, so far as is known, it never infects the human subject. The natural disease, which occurs especially in certain localities, affects chiefly sheep, cattle, and goats. Infection takes place by some wound of the surface, and then spreads in the region around, inflammatory swelling attended by bloody œdema and emphysema of the tissues. The part becomes greatly swollen, and of a dark, almost black, colour. Hence the name "black-quarter" by which the disease is often known. The bacillus which produces this condition is present in large numbers in the affected tissues, associated with other organisms, and also occurs in small numbers in the blood of internal organs.

The bacillus morphologically closely resembles that of malignant œdema. Like the latter, also, it is a strict anaerobe, and its conditions of growth as regards temperature are also similar. It is, however, somewhat thicker, and does not usually form long filaments; occasionally it occurs in short chains. The spores, which are of oval shape and broader than the bacillus, are usually subterminal, though central-spored clostridium forms occur (Fig. 133). This bacillus is actively motile, and possesses numerous lateral flagella. The characters of the cultures, also, resemble those of the bacillus of malignant œdema, but in a stab culture in glucose agar there are more numerous and longer lateral offshoots, the growth being also more luxuriant (Fig. 131, C). The superficial colonies are small greyish rounded discs with a thicker centre; the deep colonies show a radiating appearance at the periphery. M'Intosh finds that the organism belongs to the non-proteolytic class. It produces acid clot in milk in three to four days and ferments glucose, maltose, lactose, and saccharose, but not inulin or dulcite. It does not liquefy coagulated serum.

The disease can be readily produced in various animals, *e.g.*, guinea-pigs by inoculation with the affected tissues of diseased animals, and also by means of pure cultures, though an intramuscular injection of a considerable amount of the latter is sometimes necessary. The condition produced in this way closely resembles that in malignant œdema, though

there is said to be more formation of gas in the tissues. Rabbits are more resistant to this disease, whilst they are comparatively susceptible to malignant œdema. As in the case of tetanus, inoculation with living spores which have been deprived of adherent toxin by heat does not produce the disease. A toxin can be separated by filtration from cultures of bouillon containing 5 per cent. glucose and a thick emulsion of sterile calcium carbonate. It is fairly resistant to heat, withstanding two hours at 70–75° C. without being destroyed, and it is also very rapid in its action, being capable in appropriate dose of killing a horse in five minutes. It is to be noted as an important fact, that while freshly isolated cultures possess a high degree of virulence they may have little capacity for toxin production *in vitro*. Grassberger and Schattenfroh state that there may be an antagonism between maximum virulence and maximum toxin production. One of the properties of the toxin is said to be a capacity for killing leucocytes.

The disease is one against which immunity can be produced in various ways, and methods of preventive inoculation have been adopted in the case of animals liable to suffer from it. This subject was specially worked out by Arloing, Cornevin, and Thomas, and later by others. Immunity may be produced by injection (especially by the intravenous and intraperitoneal routes) with a non-fatal dose of the virus (*i.e.*, the œdematous fluid found in the tissues of affected animals and which contains the bacilli), or by injection with larger quantities of the virus attenuated by heat, drying, etc. It can be produced also by cultures attenuated by heat and by the products of the bacilli obtained by filtration of cultures. An antitoxin has been produced against the toxins of the bacillus, and a method of protection in which the action of this antitoxin is combined with that of the virus has been used (*cf.* Anthrax, p. 349). The antitoxin is said to increase the chemiotactic properties of the leucocytes.

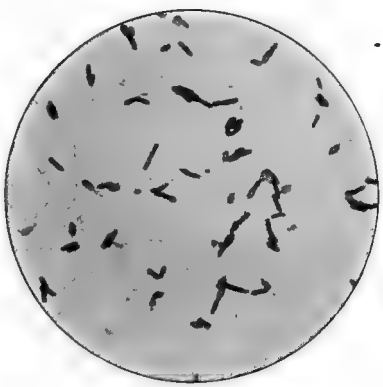

FIG. 133.—Bacillus of quarter-evil, showin spores. From a culture in glucose agar, incubated for three days at 37° C. Stained with weak carbol-fuchsin. ×1000.

FUSIFORM ANAEROBIC BACILLI PATHOGENIC TO MAN.

Babés in 1884 described organisms of this type in a diphtheria-like affection of the fauces, and since that time the presence of similar organisms has been noted in necrotic inflammations, ulcerative stomatitis, noma, and like affections. They have also been found in pulmonary lesions and in abscesses in other parts of the body; in these the pus is very foul-smelling.

The association of fusiform bacilli with a form of angina has been specially recognised since the work of Vincent (1898–99); and this condition often goes now under the name of "Vincent's angina." He recognised two forms of the affection—(*a*) a diphtheroid type, characterised by the formation of a firm yellowish-white false membrane, very like that of diphtheria, associated with only superficial ulceration; and (*b*) an ulcerative type, where the membrane is soft, greyish, and foul-smelling, attended with ulceration and surrounding œdema. In the

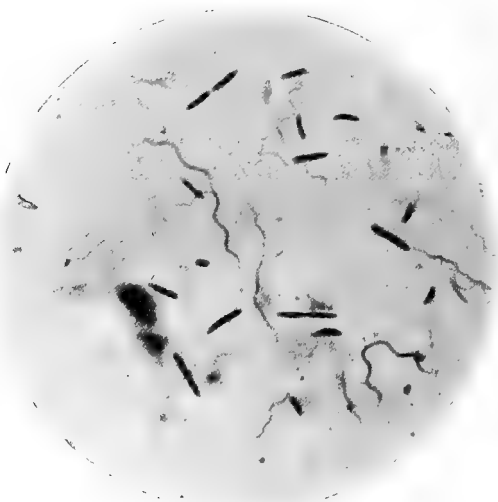

FIG. 134.—Film preparation from a case of Vincent's angina, showing fusiform bacilli and spirochætes. Stained with weak carbol-fuchsin. ×1000.

former type fusiform bacilli are present alone; in the latter, which is distinctly the commoner, there are also spirochætes. The fusiform bacilli are thin rods measuring on the average 10 to 14 μ in length, and less than 1 μ in thickness; they are straight or slightly curved and are tapered at their extremities. The central portion often stains less deeply than the extremities, and not infrequently shows unstained points and granules (Fig. 134; Plate I., Fig 4). The organisms are non-motile. They stain fairly deeply with Löffler's methylene-blue or with weak carbol-fuchsin. They lose the stain in Gram's method. The spirochætes are long delicate organisms showing several

irregular curves, and are motile; in appearance they resemble the spirochæte refringens and similar organisms found in gangrenous conditions. They stain less deeply than the bacilli. Sometimes they are numerous, sometimes scanty; they seem to be similar to spirochætes found in the mouth in a variety of other conditions. In a section through the false membrane, when stained with methylene or thionin blue, there is usually to be seen a darkly stained band, a short distance below the surface, which is due to the presence of large masses of the fusiform bacilli closely packed together; neither they nor the spirochætes appear to pass deeply into the tissues. Vincent's results have been confirmed by others, and there is no doubt that fusiform bacilli, of which there are probably several species, are associated with various spreading necrotic conditions. During the war, cases of Vincent's angina have been of common occurrence and have been met with in small epidemics. Ulcerative gingivitis and stomatitis have been found to be associated with the presence of the same organisms, and in some cases these lesions precede the infection of the fauces. It would be advisable to apply the term "Vincent's disease," as suggested by Bowman, so as to include all the lesions produced by the organisms in question. In phagedenic lesions of the genitals, fusiform bacilli are usually present, with or without spirochætes, though in our experience they are as a rule of smaller size than those met with in the throat. Cultures of fusiform bacilli have been obtained by Ellermann, by Weaver and Tunnicliffe, and by others. They grow only under anaerobic conditions, and the best media are those consisting of a mixture of serum or blood and agar (1 : 3). The organisms form small rounded colonies of whitish or yellowish colour, somewhat like those of a streptococcus, but rather felted in appearance on the surface. Injections of pure cultures in animals sometimes produce suppuration but never necrosis (Ellermann). Tunnicliffe finds that the spirochætes are only stages in the development of fusiform bacilli, as cultures which at an early stage show only fusiform bacilli, afterwards contain spirochætes, and intermediate forms can be found. There seems to be no doubt that in cultures the bacilli grow out into long filaments which may have an undulated appearance; but it is doubtful whether these are to be regarded as true spirochætes, and still more whether they are the same spirochætes as those seen in the lesions in association with the bacilli. It is also to be noted that fusiform bacilli are sometimes present in the secretions of the mouth in normal conditions, and may occur in increased numbers in true diphtheria.

CHAPTER XVIII.

THE CHOLERA SPIRILLUM AND ALLIED ORGANISMS.

Introductory.—It is no exaggeration of the facts to say that previously to 1883 practically nothing of value was known regarding the nature of the virus of cholera. In that year Koch discovered the organism now generally known as the "comma bacillus" or the "cholera spirillum." He obtained pure cultures of the organism from a large number of cases of cholera, and described their characters. The results of his researches were given at the first Cholera Conference at Berlin in 1884.

Since Koch's discovery, and especially during the epidemic in Europe in 1892–93, spirilla have been cultivated from cases of cholera in a great many different localities, and though this extensive investigation has revealed the invariable presence in true cholera of organisms resembling more or less closely Koch's spirillum, certain variations have been found. And, further, spirilla which closely resemble Koch's cholera spirillum have been cultivated from sources other than cases of true cholera. There has therefore been much controversy, on the one hand, as to the signification of these variations—whether they are to be regarded as indicating distinct species or merely varieties of the same species—and, on the other hand, as to the means of distinguishing the cholera spirillum from other species which resemble it. These questions will be discussed below.

In considering the bacteriology of cholera, it is to be borne in mind that in this disease, in addition to the evidence of great intestinal irritation, accompanied by profuse watery discharge, and often by vomiting, there are also symptoms of general systemic disturbance which cannot be accounted for merely by the withdrawal of water and certain substances from the system. Such symptoms include the profound general prostration, cramps in the muscles, extreme cardiac depression, the cold and clammy condition of the surface, the subnormal

temperature, suppression of urine, etc. These, taken in their entirety, are indications of a general poisoning in which the circulatory and thermo-regulatory mechanisms are specially involved. In some, though rare, cases known as *cholera sicca*, general collapse occurs with remarkable suddenness, and is rapidly followed by a fatal result, whilst there is little or no evacuation from the bowel, though *post mortem* the intestine is distended with fluid contents. As the characteristic organisms in cholera are present mainly in the intestine, the general disturbances are to be regarded as the result of toxic substances absorbed from the bowel. It is also to be noted that cholera is a disease of which the onset and course are much more rapid than is the case in most infective diseases, such as typhoid and diphtheria; and also that recovery, when it takes place, does so more quickly. The two factors to be correlated to these facts are: (*a*) a rapid multiplication of organisms, (*b*) the production of rapidly acting toxins.

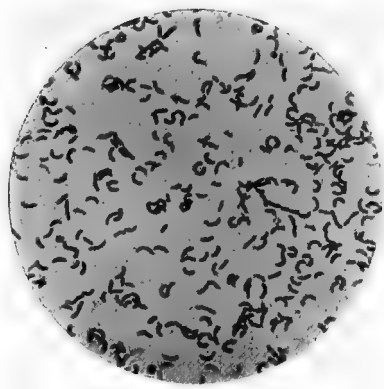

FIG. 135.—Cholera spirilla, from a culture on agar of twenty-four hours' growth. Stained with weak carbol-fuchsin. ×1000.

The Cholera Spirillum.—*Microscopical Characters.*—The cholera spirilla, as found in the intestines in cholera, are small organisms measuring about 1·5 to 2 μ in length, and rather less than ·5 in thickness. They are distinctly curved in one direction, hence the appearance of a comma (Fig. 135); most occur singly, but some are attached in pairs and curved in opposite directions, so that an S-shape results. Longer forms are rarely seen in the intestine, but in cultures in fluids, as may be well seen in hanging-drop preparations, they may grow into spiral filaments, showing a large number of turns. In film preparations made from the intestinal contents in typical cases, these organisms are present in enormous numbers in almost pure culture, most of the spirilla lying with their long axes in the same direction, so as to give the appearance which Koch compared to a number of fish in a stream.

They possess very active motility, which is most marked in the single forms, and this is due to a single terminal flagellum (Fig. 136). It is very delicate, and measures four or five times the length of the organism. Cholera spirilla do not form spores. In old cultures the organisms may present great variety in size and shape. Some are irregularly twisted filaments, sometimes globose, sometimes clubbed at their extremities, and also showing irregular swellings along their course; others are short and thick, and may have the appearance of large cocci, often staining faintly. All these changes in appearance are to be classed together as *involution forms.* (Fig. 137.)

FIG. 136.—Cholera spirilla stained to show the terminal flagella. See also Plate IV., Fig. 19. ×1000.

Staining. — Cholera spirilla stain readily with the usual basic aniline stains, though Löffler's methylene-blue or weak carbol-fuchsin is specially suitable. They are Gram-negative.

Distribution within the Body.—The chief fact in this connection is that the spirilla are practically confined to the intestine. Recent observations show that they may be found sometimes in the internal organs, and especially in the gall-bladder and

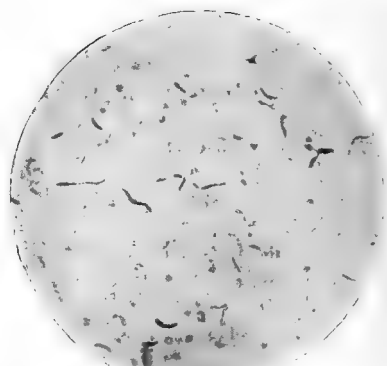

FIG. 137.—Cholera spirilla from an old agar culture, showing irregularities in size and shape, with numerous faintly-stained coccoid bodies—involution forms. Stained with fuchsin. ×1000.

biliary passages. Greig found, in a large series of post-mortem examinations, that the cholera organism was present in the gall-bladder in more than a quarter of the cases, and that, in a considerable number of these, distinct pathological changes were present. He has found it also in the urine, lungs, and spleen. Another interesting fact observed by him was that in rabbits inoculated intravenously with the living organism for the purpose of obtaining agglutinating sera, infection of the gall-bladder and the formation of gall-stones not infrequently occurred. The all-important factor in the pathology of the disease, however, is the absorption of toxins from the bowel. In cases in which there is the characteristic "rice-water" fluid in the intestines, they occur in enormous numbers—almost in pure culture. The lower half of the small intestine is the part most affected. Its surface epithelium becomes shed in great part, and the flakes floating in the fluid consist chiefly of masses of epithelial cells and mucus, amongst which are numerous spirilla. The spirilla also penetrate the follicles of Lieberkühn, and may be seen lying between the basement membrane and the epithelial lining, which becomes loosened by their action. In some very acute cases there may be relatively little desquamation of epithelium, the intestinal contents being a comparatively clear fluid containing the spirilla in large numbers. In other cases of a more chronic type, the intestine may show more extensive necrosis of the mucosa and a considerable amount of hæmorrhage into its substance, along with formation of false membrane at places. The intestinal contents in such cases are blood-stained and foul-smelling, there being a great proportion of other organisms present besides the cholera spirilla (Koch).

Cultivation.—(For methods, see p. 474.)

The cholera spirillum grows readily on all the ordinary media, and, with the exception of that on potato, growth takes place at the ordinary room temperature. The most suitable temperature, however, is that of the body, and growth usually stops about 16° C., though in some cases it has been obtained at a lower temperature. Abundant growth occurs on media with sufficiently alkaline reaction to inhibit the growth of many intestinal bacteria, *e.g.*, Dieudonné's medium, p. 46.

Peptone Gelatin.—On this medium the organism grows well and produces liquefaction. In puncture cultivations at 22° C. a whitish line appears along the needle track, at the upper part of which liquefaction commences, and as evaporation quickly occurs, a small bell-shaped depression forms, which gives the appearance of an air-bubble. On the fourth or fifth day we get

the following appearance: There is at the surface the bubble-shaped depression; below this there is a funnel-shaped area of liquefaction, the fluid being only slightly turbid, but showing at its lower end thick masses of growth of a more or less spiral shape in the thin line of liquefaction (Fig. 138). (This appearance is, however, in some varieties not produced till much later, especially when the gelatin is very stiff, and, in other varieties which liquefy very slowly, may not be met with at all.) At a later stage liquefaction spreads and may reach the side of the tube. When the organism is sub-cultured over a long period of time, it may lose to a large extent the property of liquefying gelatin.

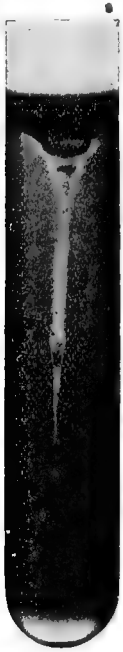

FIG. 138. — Puncture culture of the cholera spirillum in peptone gelatin — six days' growth. Natural size.

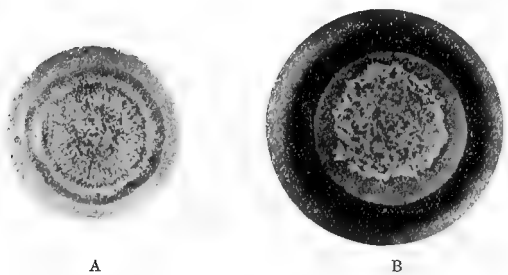
In *gelatin plates* the colonies are somewhat characteristic. They appear as minute whitish points, visible in twenty-four to forty-eight hours, the surface of which, under a low power of the microscope, is irregularly granular or furrowed (Fig. 139, A). Liquefaction occurs, and the colony sinks into the small cup formed, the plate then showing small sharply-marked rings around the colonies. Under the microscope the outer margin of the cup is circular and sharply marked. Within the cup the liquefied portion forms a ring which has a more or less granular appearance, whilst the mass of growth in the centre is irregular and often broken up at its margins (Fig. 139, B).

On the surface of *agar* media a thin, almost transparent, layer forms, which presents no special characters. On solidified *blood serum* the growth has at first the same appearance, but afterwards liquefaction of the medium occurs. On agar plates the superficial colonies under a low power are circular discs of brownish-yellow colour, and more transparent than those of most other organisms. On *potato* at the ordinary temperature, growth does not take place, but on incubation at a temperature of from 30° to 37° C. a moist layer appears, which assumes a dirty brown colour, somewhat like that of the glanders bacillus; the appearance, however, varies some-

what with different varieties, and also on different sorts of potatoes.

In *bouillon* with alkaline reaction the organism grows very readily, there occurring in twelve hours at 37° C. a general turbidity, while the surface shows a thin pellicle composed of spirilla in a very actively motile condition. Growth takes place under the same conditions equally rapidly in peptone solution (1 per cent. with ·5 per cent. sodium chloride added). It usually produces acid, without gas formation, from glucose, saccharose, mannite, and maltose; fermentation of lactose, with acid production, occurs late, namely, after two to three days.

In *milk* also the organism grows well, and produces no



A B

FIG. 139.—Colonies of the cholera spirillum on a gelatin plate—three days' growth. A shows the granular surface, liquefaction just commencing; in B liquefaction is well marked.

coagulation nor any change in its appearance, at least for several days.

On all the media the growth of the cholera spirillum is a relatively rapid one, and especially is this the case in peptone solution and in bouillon, a circumstance of importance in relation to its separation in cases of cholera (*vide* p. 475).

The cholera organism is one which grows much more rapidly in the presence of oxygen than in anaerobic conditions; in the complete exclusion of oxygen very little growth occurs.

Cholera-Red Reaction.—This is always given by a true cholera spirillum, and though the reaction is not peculiar to it, the number of organisms which give the reaction under the conditions mentioned are comparatively few. The test is made by adding a few drops of pure sulphuric acid to a culture in bouillon or in peptone solution (1 per cent.) which has been incubated for twenty-four hours at 37° C.; in the case of the cholera spirillum a reddish-pink colour is produced. This is due

to the fact that both indol and a nitrite are formed by the spirillum in the medium, and hence, in applying the test for indol, the addition of a nitrite is not necessary. It is essential that the sulphuric acid should be pure, for if traces of nitrites are present the reaction may be given by an organism which has not the power of forming nitrites.

Hæmolytic Test.—This method, introduced by Kraus, is performed by means of agar plates (p. 45), a small quantity of sterile defibrinated blood being added to the agar and thoroughly diffused; if any organism has hæmolytic properties, a clear zone or areola forms around each colony by the diffusion of hæmoglobin. As a rule the cholera organism does not produce hæmolysis, but the result after twenty-four hours should be taken, as later a clear zone may appear round a cholera colony (Greig). It has, however, been found by several observers that the hæmolytic test is best carried out with a fluid culture. Greig, for example, adds varying amounts, from 1 c.c. downwards, of a three days' culture in alkaline broth to 1 c.c. of a 5 per cent. suspension of goats' corpuscles, the whole being made up to 2 c.c., and thoroughly mixed. The tubes are placed in the incubator for two hours at 37° C., and then in the ice-chest overnight, the results being read next day. He found after testing more than 300 strains of true cholera spirilla that none of them produced hæmolysis, whereas this results with organisms of the El Tor group (*vide infra*).

Powers of Resistance.—In their resistance against heat, cholera spirilla correspond with most spore-free organisms, and are killed in an hour by a temperature of 55° C., and much more rapidly at higher temperatures. They have comparatively high powers of resistance against great cold, and have been found alive after being exposed for several hours to the temperature of −10° C. They are, however, killed by being kept in ice for a few days. Against the ordinary antiseptics they have comparatively low powers of resistance, and Pfuhl found that the addition of lime, in the proportion of 1 per cent., to water containing the cholera organisms was sufficient to kill them in the course of an hour.

As regards the powers of resistance in ordinary conditions, the following facts may be stated: In cholera stools kept at the ordinary room temperature, the cholera organisms are rapidly outgrown by putrefactive bacteria, but in exceptional cases they have been found alive even after two or three months. In most experiments, however, attempts to cultivate them even after a much shorter time have failed. The general conclusion may be drawn from the work of various observers, that the spirilla do not multiply freely in ordinary sewage water, although they may remain alive for a considerable period of time. On moist linen, as Koch showed, they can flourish very rapidly. Though we

can state generally that the conditions favourable for the growth of the cholera spirillum are a warm temperature, moisture, a good supply of oxygen, and a considerable proportion of organic material, we do not know the exact circumstances under which it can flourish for an indefinite period of time as a saprophyte. The fact that the area in which cholera is an endemic disease is so restricted, tends to show that the conditions for a prolonged growth of the spirillum outside the body are not usually supplied. During recent epidemics the cholera organism has been cultivated from the stools of a considerable number of people suffering from slight intestinal disturbance, and even from the stools of quite healthy individuals; these may be regarded as "cholera-carriers." Numerous observations, carried out both on convalescents and on contacts having the spirillum in the stools, show that in the great majority of cases it dies out after two or three weeks and usually earlier; it has, however, been found as long as twelve months afterwards. Greig has found that the excretion of the organism in the stools of carriers is of an intermittent character; accordingly several examinations are necessary before they can be pronounced free. There is no doubt that carriers play an important part in the spread of the disease, and can originate epidemics.

Cholera organisms are, as a rule, rapidly killed by being thoroughly dried, and it is inferred from this that they cannot be carried in the living condition for any great distance through the air, a conclusion which is well supported by observations on the spread of the disease. Cholera is practically always transmitted by means of water or food contaminated by the organism, and there is no doubt that contamination of the water supply by choleraic discharges is the chief means by which areas of population are rapidly infected. It has been shown that if flies are fed on material containing cholera organisms, the organisms may be found alive within their bodies twenty-four hours afterwards. And further, Haffkine found that sterilised milk might become contaminated with cholera organisms if kept in open jars to which flies had free access, in a locality infected by cholera. It is quite possible that infection may be carried by this agency in some cases.

Experimental Inoculation.—In considering the effects of inoculation with the cholera organism, we are met with the difficulty that none of the lower animals, so far as is known, suffer from the disease under natural conditions. Accordingly, attempts to induce the multiplication of the organism within the intestine of animals by artificially arranging favouring

conditions occupied a prominent place in the early experimental work. We shall give a short account of such experiments :—

Nikati and Rietsch were the first to inject the organisms directly into the duodenum of dogs and rabbits, and they succeeded in producing, in a considerable proportion of the animals, a choleraic condition of the intestine. These experiments were confirmed by other observers, including Koch. Thinking that probably the spirillum, when introduced by the mouth, is destroyed by the action of the hydrochloric acid of the gastric secretion, Koch first neutralised this acidity by administering to guinea-pigs 5 c.c. of a 5 per cent. solution of carbonate of soda, and some time afterwards introduced a pure culture into the stomach by means of a tube. As this method failed to give positive results, he tried the effect of artificially interfering with the intestinal peristalsis by injecting tincture of opium into the peritoneum (1 c.c. per 200 grm. weight), in addition to neutralising as before with the carbonate of sodium solution. The result was remarkable, as thirty out of thirty-five animals treated died with symptoms of general prostration and collapse. Death occurs after a few hours. *Post mortem* the small intestine is distended, its mucous membrane congested, and it contains a colourless fluid with small flocculi and the cholera organisms in practically pure cultures. Koch, however, found that when the spirilla of Finkler and Prior, of Deneke, and of Miller (*vide infra*) were employed by the same method, a certain, though much smaller, proportion of the animals died from an intestinal infection. Though the changes in these cases were not so characteristic, they were sufficient to prevent the results obtained with the cholera organism from being used as a demonstration of the specific relation of the latter to the disease.

Some additional facts with regard to choleraic infection of animals may be mentioned. For example, Sabolotny found that in the marmot an intestinal infection readily takes place by simple feeding with the organism, there resulting the usual intestinal changes, sometimes with hæmorrhagic peritonitis—the organisms, however, being present also in the blood. And of special interest is the fact, discovered by Metchnikoff, that in the case of young rabbits shortly after birth a large proportion die of choleraic infection when the organisms are simply introduced along with the milk, as may be done by infecting the teats of the mother. Further, from these animals thus infected the disease may be transmitted to others by a natural mode of infection. In this affection of young rabbits many of the symptoms of cholera are present. Many of these experiments were performed with the vibrio of Massowah, which is now admitted not to be a true cholera organism, others with a cholera vibrio obtained from the water of the Seine.

It will be seen from the above account that the evidence obtained from experiments on intestinal infection of animals, though by no means sufficient to establish the specific relationship of the cholera organism, is on the whole favourable to this view, especially when it is borne in mind that animals do not in natural conditions suffer from the disease.

Experiments performed by direct inoculation also supply

interesting facts. *Intraperitoneal* injection in guinea-pigs is followed by general symptoms of illness, the most prominent being distension of the abdomen, subnormal temperature, and, ultimately, profound collapse. There is peritoneal effusion, which may be comparatively clear, or may be somewhat turbid and contain flakes of lymph, according to the stage at which death takes place. If the dose is large, organisms are found in considerable numbers in the blood and also in the small intestine, but with smaller doses they are practically confined to the peritoneum. Kolle found that when the minimum lethal dose was used in guinea-pigs, the peritoneum might be free from living organisms at the time of death, the fatal result having taken place from an intoxication (*cf.* Diphtheria, p. 407). These and other experiments show that though the organisms undergo a certain amount of multiplication when introduced by the channels mentioned, still the tendency to invade the tissues is not a marked one. On the other hand, the symptoms of general intoxication are always pronounced.

Experiments on the Human Subject.—Experiments have also been performed in the case of the human subject, both intentionally and accidentally. In the course of Koch's earlier work, one of the workers in his laboratory shortly after leaving was seized with severe choleraic symptoms. The stools were found to contain cholera spirilla in enormous numbers. Recovery, however, took place. In this case there was no other possible source of infection than the cultures with which the man had been working, as no cholera was present in Germany at the time. A considerable number of experiments have been performed on the human subject, which certainly show that in some cases more or less severe choleraic symptoms may follow ingestion of pure cultures, whilst in others no effects may result. The former was the case, for example, with Emmerich and Pettenkofer, who made experiments on themselves, the former especially becoming seriously ill. In the case of both, diarrhœa was well marked, and numerous cholera spirilla were present in the stools, though toxic symptoms were proportionately little pronounced. Metchnikoff also, by experiments on himself and others, obtained results which convinced him of the specific relation of the cholera spirillum to the disease. Lastly, we may mention the case of Dr. Örgel in Hamburg, who contracted the disease in the course of experiments with the cholera and other spirilla, and died in spite of treatment. It is believed that in sucking up some peritoneal fluid containing cholera spirilla, a little entered his mouth and thus infection was produced. This

took place in September 1894, at a time when there was no cholera in Germany. On the other hand, in many cases the experimental ingestion of cholera spirilla by the human subject has given negative results. Still, as the result of observation of what takes place in a cholera epidemic and of what has been established with regard to cholera carriers, we may consider that only a certain proportion of people are very susceptible to cholera, and the facts just mentioned are, in our opinion, of the greatest importance in establishing the relation of the organism to the disease.

Toxins.—The general statement may be made that filtered cholera cultures as a rule have little toxic action—that is, comparatively little extracellular toxin is produced by the organism. It was, however, shown by R. Pfeiffer that the dead spirilla were highly toxic, and that, in fact, they produced, on injection into guinea-pigs, the same phenomena as living cultures, profound collapse with subnormal temperature being a prominent feature. Pfeiffer considers that the toxic substances are contained in the bodies of the organisms,—that is, they are *endotoxins*,—and that they are only set free by the disintegration of the latter. He showed also that when an animal is inoculated intraperitoneally with the cholera organism, and then some time later anti-cholera serum which produces bacteriolysis is injected, rapid collapse with a fatal result may ensue, apparently due to the liberation of the endotoxins. The dead cultures administered by the mouth produce no effect unless the intestinal epithelium is injured, in which case poisoning may result. He considers that the desquamation of the epithelium is an essential factor in the production of the phenomena of the disease in the human subject. Pfeiffer found that the toxic bodies were to a great extent destroyed at 60° C., but even after heating at 100° C. a small proportion of toxin remained, which had the same kind of action. Later, A. Macfadyen found that the product obtained by grinding up the spirilla frozen by means of liquid air, had a very high degree of toxicity when injected intravenously. Like Pfeiffer, he found that the "endotoxin" was in great part destroyed at 60° C.

On the other hand, other observers (Petri, Ransom, Klein, and others) have obtained toxic bodies from *filtered cultures*. Metchnikoff, E. Roux, and Taurelli-Salimbeni have demonstrated the formation of such diffusible toxic bodies in fluid media. By means of cultures placed in collodion sacs in the peritoneum of animals, they found that the living organisms produce toxic bodies which diffuse through the wall of the sac and cause toxic symptoms. By greatly increasing the virulence of the organism, then growing it in bouillon and filtering the cultures on the third and

fourth day, they obtained a fluid which was highly toxic to guinea-pigs (the fatal dose usually being ½ c.c. per 100 grm. weight). The symptoms closely resemble those obtained by Pfeiffer. They found that the toxicity of the filtrate was not altered by boiling—apparently this toxic substance is different from Pfeiffer's endotoxin. Huntemüller has obtained from various strains an acutely acting extracellular toxin which is very labile and which he believes to be identical with the hæmolysin. He has obtained an antitoxin to this toxin. The diversity in the results obtained by various workers seems only explicable on the view that different strains vary greatly as regards production of extracellular toxin. It may be stated that, as a rule, the greater part of the toxic substance is closely bound up with the bacterial protoplasm, and is only set free on its disintegration.

Immunity.—As this subject is discussed later, only a few facts will be here stated, chiefly for the purpose of making clear what follows with regard to the means of distinguishing the cholera spirillum from other organisms. The guinea-pig or any other animal may be easily immunised against the cholera organism by repeated injections (conveniently made into the peritoneum) of non-fatal doses of dead spirilla; later the living organisms may be used. In this way a high degree of immunity against the organism is developed; and further, the blood serum of an animal thus immunised (anti-cholera serum) has markedly protective power when injected, even in a small quantity, into a guinea-pig along with five or ten times the fatal dose of the living organism. Under these circumstances the spirilla undergo a granular transformation and, ultimately, solution; this phenomenon is generally known as Pfeiffer's reaction, and was applied by him to distinguish the cholera spirillum from organisms resembling it. The following are the details :—

Pfeiffer's Reaction.—A loopful (2 mgrm.) of a recent agar culture of the organism to be tested is added to 1 c.c. of ordinary bouillon containing ·001 c.c. of anti-cholera serum. The mixture is then injected into the peritoneal cavity of a young guinea-pig (about 200 grm. in weight), and the peritoneal fluid of this animal (conveniently obtained by means of capillary glass tubes inserted into the peritoneum) is examined microscopically after a few minutes. If the spirilla injected have been cholera spirilla, it will be found that they become motionless, swell up into globules, and ultimately break down and disappear—*positive result*. If they are found active and motile, then the possibility of their being true cholera spirilla may be excluded—*negative result*. In the former case (positive result) there is, however, still the possibility that the organism is devoid of pathogenic properties and has been destroyed by the normal peritoneal fluid. A control experiment should accordingly be made with ·001 c.c. of normal serum in place of the anti-cholera serum. If no alteration of the organism occurs with its use, then the conclusion is that a true reaction has been given. Corresponding bacteriolytic effects may be obtained by *in vitro* methods, introduced since Pfeiffer's original method.

The serum of an animal immunised by the above method has also marked agglutinative and other antibacterial properties (p. 571) against the cholera spirillum, and these properties closely correspond with Pfeiffer's reaction as regards specificity. Such a serum has, however, little protective effect against the toxic action of the dead spirilla, and Pfeiffer maintained that little or no antitoxin to the endotoxin can be produced. On the other hand, Macfadyen, by injecting the endotoxin derived from the spirilla by grinding, obtained a serum which had antitoxic as well as agglutinative and bacteriolytic properties (*vide* Immunity). Metchnikoff and others also obtained antitoxic sera which acted on the extracellular toxins. While it may be admitted that antitoxins to some of the cholera toxins may be obtained, yet Pfeiffer's position, that cholera anti-sera have little effect on at least most of the endotoxins, cannot be said to be shaken. It should be noted, however, that he disclaims having made the general statement, often ascribed to him, that no antitoxins are formed to endotoxins.

The *serum of cholera convalescents* has been found to possess protective and increased bactericidal action. These properties of the serum may be present eight or ten days after the attack of the disease, but are most marked four weeks after; they then gradually diminish. Specific agglutinative properties appear in the serum of cholera patients, as in other diseases. They are most marked in patients who recover, reaching the maximum in from two to three weeks from the onset of the disease, the serum then agglutinating in a dilution of 1 : 400 or even 1 : 1000 (Greig). Agglutinins are also often present in the blood of carriers. It should, however, be noted that normal serum may sometimes have an agglutinating effect on the cholera organism in a dilution as high as 1 : 20. Variations in the opsonic index, analogous to those in other diseases, have been observed in cholera, a marked fall on the acute onset of the disease being a noteworthy feature.

Within recent times there have been introduced for therapeutic purposes several so-called anti-sera which are supposed to be antitoxic as well as anti-bacterial, and of these the two most extensively used are those of Kraus and Schurupoff. Reports regarding the effects of these sera are of somewhat conflicting character, but in any case it cannot be said that they have a markedly beneficial action. They have further been critically examined by others, who deny to them any marked antitoxic action when tested experimentally.

Allied Organisms.—*El Tor Vibrio.*—Up till recent times there had been cultivated, from sources other than cholera cases,

no organism which gave all the cultural and serum tests (agglutination and Pfeiffer's reaction) of the cholera spirillum. In 1905, however, Gotschlich obtained six different strains of a spirillum which conformed in all these respects. The organisms were obtained at El Tor from the intestines of pilgrims who had died with dysenteric symptoms, and there were no cases of cholera in the vicinity. The organisms in question, however, differ from the cholera organism in having marked hæmolytic action, and also in producing a rapidly acting extracellular toxin. Kraus and others have found, on comparing anti-sera to the cholera and El Tor spirilla, that while the anti-bacterial properties are similar there is a difference in antitoxic action. The El Tor antitoxin neutralises the cholera toxin, but a cholera antitoxin has no effect on the El Tor toxin; the El Tor spirillum is thus peculiar as regards its toxic products. There is accordingly difference of opinion as to whether these organisms are to be regarded as a distinct species or as true cholera spirilla. In view, however, of what we know of variations in the type of the cholera organism, the latter possibility is probably the case.

Paracholera.—More recent observations have shown that there occur groups of cases with choleraic symptoms or merely diarrhœa, in which the spirilla present differ in certain respects from the cholera spirillum. Such cases have been studied especially in India and Egypt, and the term paracholera has been applied. To speak generally, the symptoms are milder than those of true cholera, fatal results being comparatively rare, and the infection does not tend to spread as an epidemic. In addition to those suffering from the disease, similar organisms have been obtained from the stools of contacts—that is, carriers occur. In those affected, the spirilla are often present in the stools in large numbers, and on isolation are found to have the morphological and cultural characters of the cholera spirillum; they are also virulent to the guinea-pig on intra-peritoneal injection. They are, however, markedly hæmolytic, when tested both on blood-agar plates and with suspensions of red corpuscles. Further, they differ serologically from the cholera organism—they are not agglutinated by an anti-cholera serum and they react negatively in Pfeiffer's reaction. They also differ serologically amongst themselves, and several varieties may in this way be distinguished (Mackie). In this group of organisms, producing relatively a mild form of disease, we have manifestly a close analogy to the case of the paratyphoid bacilli.

Anti-Cholera Inoculation.—Haffkine's method for inoculation against cholera exemplifies the above principles. It depends

upon (*a*) attenuation of the virus—that is, the cholera organism, and (*b*) exaltation of the virus. The virulence of the organism is diminished by passing a current of sterile air over the surface of the cultures, or by various other methods. The virulence is exalted by the method of *passage*—that is, by growing the organism in the peritoneum in a series of guinea-pigs. By the latter method the virulence after a time is increased twentyfold —that is, the fatal dose has been reduced to a twentieth of the original. Cultures treated in this way constitute the *virus exalté*. Subcutaneous injection of the *virus exalté* produces a local necrosis, and may be followed by the death of the animal, but if the animal be treated first with the attenuated virus, the subsequent injection of the *virus exalté* produces only a local œdema. After inoculation first by attenuated and afterwards by exalted virus, the guinea-pig has acquired a high degree of immunity; and Haffkine believed that this immunity was effective in the case of every method of inoculation—that is, by the mouth as well as by injection into the tissues. After trying his method on the human subject and finding it free from risk, he extended it in practice on a large scale in India in 1894. In the human subject two or sometimes three inoculations were formerly made with attenuated virus before the *virus exalté* was used; now, however, a single injection of the latter is usually practised. The results of preventive inoculation in India and in Russia have been such as to establish its efficiency, both the case incidence and the mortality being reduced.

Methods of Diagnosis.—In the first place, the stools ought to be examined microscopically. Dried film preparations should be made and stained by any ordinary stains, though carbol-fuchsin diluted four times with water is specially to be recommended. Hanging-drop preparations, with or without the addition of a weak watery solution of gentian-violet or other stain, should also be made, by which method the motility of the organism can be readily seen. By microscopic examination the presence of spirilla will be ascertained, and an idea as to their number obtained. In some cases the cholera spirilla are so numerous in the stools that a picture is presented which is obtained in no other condition, and a microscopic examination may be sufficient for practical purposes. According to Koch, a diagnosis was made in 50 per cent. of the cases during the Hamburg epidemic by microscopic examination alone. In the case of the first appearance of a cholera-like disease, however, all the other tests should be applied before a definite diagnosis of cholera is made.

If the organisms are very numerous, agar plates or plates of Dieudonné's medium (p. 46) may be inoculated at once and a pure culture obtained from one of the colonies.

If the spirilla occur in comparatively small numbers, the best method is to inoculate peptone solution (1 per cent.) and incubate for from six to eight hours. At the end of that time the spirilla will be found on microscopic examination in enormous numbers at the surface, and thereafter plate cultures can readily be made. If the spirilla are very few in number, or if a suspected water is to be examined for cholera organisms, the peptone solution which has been inoculated should be examined at short intervals till spirilla are found microscopically. A second flask of peptone solution should then be inoculated, and possibly again a third from the second, and then plates may be made. In such circumstances Dieudonné's medium has been found of much service. For the separation of the organism Ottolenghi introduced a medium composed of ox-bile to which 3 per cent. of a 10 per cent. solution of sodium carbonate is added: it is sterilised in the autoclave. It is used in the same way as peptone solution, and the advantage claimed for it is, that it inhibits the growth of most intestinal bacteria; on the other hand, the cholera organism appears to grow rather less rapidly than in peptone solution.

When a spirillum has been obtained in pure condition by these methods it should be tested, as regards agglutination against a high titre anti-cholera serum. If it reacts positively it may be accepted for practical purposes as the cholera organism. Thereafter the cultural characters and the hæmolytic and pathogenic properties may be tested. If it reacts negatively with anti-cholera serum it may be one of the paracholera group, and similar tests should be made.

Dunbar introduced a method for rapid diagnosis which depends on the properties of an anti-cholera serum. Two hanging-drop preparations are made, each consisting of a small portion of mucus from the suspected stool broken up in peptone solution. To one a drop of a 50-fold dilution of normal serum is added, to the other a drop of a 500-fold dilution of an active cholera serum. If the spirilla present are cholera organisms, they retain their motility in the first preparation, while they lose it and then become agglutinated in the second. By this method a diagnosis may sometimes be given in a few minutes. Others have adopted the method of growing the suspected organism in bouillon containing a small amount of anti-cholera serum; in the case of the cholera organism growth falls to the bottom as a

sediment, leaving the fluid clear. All such methods, however, require considerable experience on the part of the observer.

A number of other spirilla have been cultivated, which are of interest on account of their points of resemblance to the cholera organism, though probably they produce no pathological conditions in the human subject.

Metchnikoff's Spirillum (vibrio metchnikovi).—This organism was obtained by Gamaleia from an epidemic disease of fowls in Odessa, and is of special interest on account of its close resemblance to the cholera organism.

Morphologically the organism is practically identical with Koch's spirillum (Fig. 140). It is actively motile, and has the same staining reactions. Its growth in peptone-gelatin also closely resembles that of the cholera organism, though it produces liquefaction more rapidly (Fig. 141, A). After liquefaction occurs, some of the colonies are almost identical in appearance with those of the cholera vibrio, whilst others show more uniformly turbid contents. In puncture cultures the growth takes place more rapidly, but in appearance closely resembles that of the cholera organism a few days older. Its growth in peptone solution, too, is closely similar, and it also gives the cholera-red reaction.

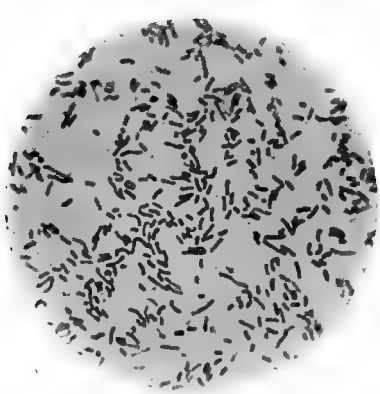


FIG. 140.—Metchnikoff's spirillum, both in curved and straight forms; from an agar culture of twenty-four hours' growth. Stained with weak carbol-fuchsin. ×1000.

This organism, can, however, be readily distinguished from the cholera organism by the effects of inoculation on animals, especially on pigeons and guinea-pigs. Subcutaneous inoculation of small quantities of pure culture in pigeons is followed by septicæmia, which produces a fatal result usually within twenty-four hours. Inoculation with the same quantity of cholera culture produces practically no result; even with large quantities death is rarely produced. The vibrio metchnikovi produces somewhat similar effects in the guinea-pig to those in the pigeon, subcutaneous inoculation being followed by extensive hæmorrhagic œdema and a rapidly fatal septicæmia. Young fowls can be infected by feeding with virulent cultures. We have evidence from the work of Gamaleia that the toxins of this organism have somewhat the same action as those of the cholera organism.

The organism is therefore one which very closely resembles the cholera organism, the results on inoculating the pigeon offering the most ready means of distinction. It gives a negative reaction to Pfeiffer's test—that

is, the properties of an anti-cholera serum are not exerted against it. It may also be mentioned that an organism which is apparently the same as the vibrio metchnikovi was cultivated by Pfuhl from water, and named v. nordhafen.

Finkler and Prior's Spirillum.—These observers, shortly after Koch's discovery of the cholera organism, separated a spirillum, in a case of *cholera nostras*, from the stools after they had been allowed to decompose for several days. There is, however, no evidence that the spirillum has any causal relationship to this or any other disease in the human subject. Morphologically it closely resembles Koch's spirillum, and cannot be distinguished from it by its microscopical characters, although, on the whole, it tends to be rather thicker in the centre and more pointed at the ends (Fig. 142). In cultures, however, it presents marked differences. In puncture cultures on gelatin it grows much more quickly, and liquefaction is generally visible within twenty-four hours. The liquefaction spreads rapidly, and usually in forty-eight hours it has produced a funnel-shaped tube with turbid contents, denser below (Fig. 141, B). In plate cultures the growth of the colonies is proportionately rapid. Before they have produced liquefaction around them, they appear, unlike those of the cholera organism, as minute spheres with smooth margins. When liquefaction occurs, they appear as little spheres with turbid contents, which rapidly increase in size; ultimately general liquefaction occurs. On potatoes this organism grows well at the ordinary temperature, and in two or three days has formed a slimy layer of greyish-yellow colour, which rapidly spreads over the potato. On all the media the growth has a distinctly fœtid odour. A growth in peptone solution fails to give the cholera-red reaction at the end of twenty-four hours, though later a faint reaction may appear.

Natural size.

An organism cultivated by Miller ("Miller's Spirillum") from the cavity of a decayed tooth in a human subject is almost certainly the same organism as Finkler and Prior's spirillum.

Deneke's Spirillum.—This organism was obtained from old cheese, and is also known as the *spirillum tyrogenum*. It closely resembles Koch's spirillum in microscopic appearances, though it is rather thinner and

smaller. Its growth in gelatin is also somewhat similar, but liquefaction proceeds more rapidly, and the bell-shaped depression on the surface is larger and shallower, whilst the growth has a more distinctly yellowish tint. The colonies in plates also show points of resemblance, though the youngest colonies are rather smoother and more regular on the surface, and liquefaction occurs more rapidly than in the case of the cholera

FIG. 142.—Finkler and Prior's spirillum; from an agar culture of twenty-four hours' growth.
Stained with carbol-fuchsin. ×1000.

organism. The colonies have, on naked-eye examination, a distinctly yellowish colour. The organism does not give the cholera-red reaction, and on potato it forms a thin yellowish layer when incubated above 30° C. When tested by intraperitoneal injection and by other methods, it is found to possess very feeble, or almost no pathogenic properties. Deneke's spirillum is usually regarded as a comparatively harmless saprophyte.

CHAPTER XIX.

INFLUENZA, WHOOPING-COUGH, PLAGUE, MALTA FEVER.

Influenza.

The first accounts of the organism now known as the influenza bacillus were published simultaneously by Pfeiffer, Kitasato, and Canon, in January 1892. The two first-mentioned observers found it in the bronchial sputum, and obtained pure cultures, and Canon observed it in the blood in a few cases of the disease. It is, however, to Pfeiffer's work that we owe most of our knowledge regarding its characters and action. His results have been amply confirmed by those of others in various epidemics of the disease, and this organism has been generally accepted as the cause of the disease, although absolute proof is still wanting.

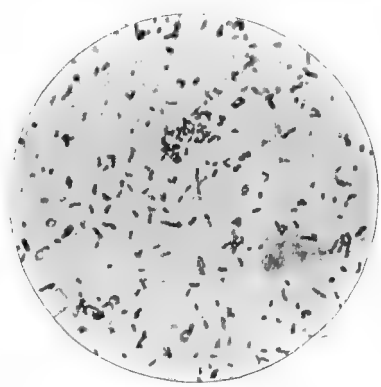

Fig. 143.—Influenza bacilli from a culture on blood-agar. Stained with carbol-fuchsin. ×1000.

Microscopical Characters.—The influenza bacilli as seen in the sputum are very minute rods not exceeding 1·5 μ in length and ·3 μ in thickness. They are straight, with rounded ends, and sometimes stain more deeply at the extremities (Fig. 143). The bacilli occur singly or form clumps by their aggregation, but do not grow into chains. They show no capsule. They take up the basic aniline stains somewhat feebly, and are best stained by a weak solution (1 : 10)

of carbol-fuchsin applied for from five to ten minutes. They are Gram-negative. They are non-motile, and do not form spores.

In many cases of the disease, especially in the early stages of the more acute, influenza bacilli are present in large numbers and may be easily found. On the other hand, it is often difficult or impossible to find them, even when the symptoms are severe; this may be due to the restriction of the organisms to some part not readily accessible, or it may be that they actually die out in great part while the effects of their toxins persist. It has also been observed in recent epidemics, in which the disease has been less widespread and on the whole less severe, that the period during which the bacilli have been readily demonstrable in the secretions has been on the average shorter than in the previous epidemics.

Cultivation.—The best medium for the growth of the influenza bacillus is blood-smeared agar (see p. 44), which was introduced by Pfeiffer for this purpose. He obtained growths of the bacilli on agar which had been smeared with influenza sputum, but he failed to get any *sub*-cultures on the agar media or on serum. The growth in the first cultures he considered to be probably due to the presence of certain organic substances in the sputum, and accordingly he tried the expedient of smearing the agar with drops of blood before making the inoculations. In this way he completely succeeded in attaining his object. The blood of the lower animals is suitable, as well as human blood; and the favouring influences of the blood would appear to be due to the hæmoglobin, as a solution of this substance is equally effective. The colonies of the influenza bacilli on blood-agar, incubated at 37° C., appear within twenty-four hours, in the form of minute circular dots almost transparent, like drops of dew. When numerous, the colonies are scarcely visible to the naked eye, but when sparsely arranged they may reach the size of a small pin's head. This size is generally reached on the second day. In cultures the bacilli may show considerable variations in size and in shape; they die out somewhat quickly, and in order to keep them alive sub-cultures should be made every four or five days. By this method the cultures may be maintained for an indefinite period. Even in sub-cultures growth on the ordinary agar media is slight and somewhat uncertain; there is, however, evidence that growth is more marked when other organisms are present—that is, is favoured by symbiosis. Neisser, for example, was able to cultivate the influenza bacillus on plain agar through several generations by growing the xerosis bacillus along with it; dead

cultures of the latter had not the same favouring effect. Allen has also noted that the growth of the influenza bacillus is aided by the concomitant growth of pneumococci and staphylococci. A very small amount of growth takes place in bouillon, but it is more marked when a little fresh blood is added. The growth forms a thin whitish deposit at the bottom of the flask. The limits of growth are from 25° to 42° C., the optimum temperature being that of the body. The influenza bacillus is a strictly aerobic organism.

The powers of resistance of this organism are of a low order. Pfeiffer found that dried cultures kept at the ordinary temperature were usually dead in twenty hours, and that if sputum were kept in a dry condition for two days, all the influenza bacilli were dead, or rather, cultures could be no longer obtained. Their duration of life in ordinary water is also short, the bacilli usually being dead within two days. From these experiments it follows that outside the body in ordinary conditions they cannot multiply, and can remain alive only for a short time. The mode of infection in the disease would thus appear to be chiefly by means of fine particles of disseminated sputum, etc.

Distribution in the Body.—The bacilli are found chiefly in the respiratory passages in influenza. They may be present in large numbers in the nasal secretion, generally mixed with a considerable number of other organisms, but it is in the small masses of greenish-yellow sputum from the bronchi that they are present in largest numbers, in many cases almost in a state of purity. They occur in clumps which may contain as many as 100 bacilli, and in the early stages of the disease are chiefly lying free. As the disease advances, they may be found in considerable numbers within the leucocytes, and towards the end of the disease a large proportion have this position. It is a matter of considerable importance, however, that they may persist for weeks after symptoms of the disease have disappeared, and may still be detected in the sputum. Especially is this the case when there is any chronic pulmonary disease. They also occur in large numbers in the capillary bronchitis and catarrhal pneumonia of influenza, as Pfeiffer showed by means of sections of the affected parts. In these sections he found the bacilli lying amongst the leucocytes which filled the minute bronchi, and also penetrating between the epithelial cells and into the superficial parts of the mucous membrane. Other organisms also, especially Fraenkel's pneumococcus, may be concerned in the pneumonic conditions following influenza. In some cases influenza occurs in tubercular subjects, or is followed by tubercular

affection, in which cases both influenza and tubercle bacilli may be found in the sputum. In such a condition the prognosis is very grave. Regarding the presence of influenza bacilli in the other pulmonary complications following influenza, much information is still required. Occasionally in the foci of suppurative softening in the lung the influenza bacilli have been found in a practically pure condition. In cases of empyema the organisms present would appear to be chiefly streptococci and pneumococci; whilst in the gangrenous conditions, which sometimes occur, a great variety of organisms has been found.

Pfeiffer's observations on a large series of cases convinced him that the organism was very rarely present in the blood—that in fact its occurrence there must be looked upon as exceptional. The conclusions of other observers have, on the whole, confirmed this statement, and it is probable that the chief symptoms in the disease are due to toxins absorbed from the respiratory tract (*vide infra*). Ghedini, however, states that he was able to cultivate the organism from the blood and spleen during life in over 50 per cent. of the cases examined: he found that its occurrence in these situations was specially frequent during marked fever. The bacillus may be present in some of the lesions complicating influenza. Pfeiffer found it in inflammation of the middle ear, and it has been frequently found in meningitis following influenza. Care must, however, be taken in such cases in differentiating the bacilli from closely allied organisms (*vide* p. 253). Pfuhl considers that in these the path of infection is usually a direct one through the roof of the nasal cavity. This observer also found *post mortem*, in a rapidly fatal case with profound general symptoms, influenza bacilli in various organs, both within and outside of the vessels. In a few cases also the bacilli have been found in the brain and its membranes with little tissue change in the parts around.

Extensive observations on the bacteriology of the respiratory system show that influenza-like bacilli may be present in a great variety of conditions; we have, in fact, once more to do with a group of organisms with closely allied characters, of which Pfeiffer's influenza bacillus was the first recognised example. These "pseudo-influenza" bacilli have been obtained from the fauces, bronchi, and lungs in inflammatory conditions, and also in various specific fevers. To this group belongs the bacillus which has been cultivated from cases of whooping-cough by Spengler, Jochmann, Davis, and others, and which is present in considerable numbers in a large proportion of cases of this disease (p. 484). Müller's "trachoma bacillus" (p. 219) is a member of the same group, as is also Cohen's bacillus of meningitis. All these organisms are very restricted in their growth, and require the addition of blood or hæmoglobin to the ordinary culture media; hence they are sometimes spoken of a *hæmophilic*

bacteria. Some of the examples are a little larger than the influenza bacillus, and tend to form short filaments, but others are quite indistinguishable. Most of them also seem to have very feeble pathogenic properties towards the lower animals. At present it can scarcely be claimed as possible to identify Pfeiffer's bacillus by its microscopic and cultural characters.

Experimental Inoculation.—There is no satisfactory evidence that any of the lower animals suffer from influenza in natural conditions, and accordingly we cannot look for very definite results from experimental inoculation. Pfeiffer, by injecting living cultures of the organism into the lungs of monkeys, in three cases produced a condition of fever of a remittent type. There was, however, little evidence that the bacilli had undergone multiplication, the symptoms being apparently produced by their toxins. He accordingly came to the conclusion that the influenza bacilli contain toxic substances which can produce in animals some of the symptoms of the disease, but that animals are not liable to *infection*, the bacilli not having power of multiplying to any extent in their tissues. In the case of rabbits, intravenous injection of living cultures produces dyspnœa, muscular weakness, and slight rise of temperature; death may follow. Wollstein distinguishes virulent and avirulent types according to the result on intravenous injection in the rabbit; the virulent types cause death in about twenty-four hours, the bacilli being numerous in the blood. The dose used, however, is comparatively large, namely, a blood-agar culture for a rabbit of 1000 grammes. Strains from the respiratory tract were non-virulent by this test; those from the blood and meninges, and rarely from pneumonic lung, were virulent. No essential difference between the strains was brought out by serological tests. Wollstein has found that a fatal cerebro-spinal meningitis can be produced in monkeys by the sub-dural injection of virulent cultures; and that, in certain circumstances, this affection may be cured by means of an anti-influenza serum obtained from the goat.

Cantani succeeded in producing infection to some extent in rabbits, by injecting the bacilli directly into the anterior portion of the brain. In these experiments the organisms spread to the ventricles, and then through the spinal cord by means of the central canal, afterwards infecting the substance of the cord. An acute encephalitis was thus produced, and sometimes a purulent condition in the lateral ventricles. The bacilli were, however, never found in the blood or in other organs. Similar symptoms were also produced by injection of dead cultures, though in this case the dose required to be five or six times larger. Cantani therefore concluded that the brain substance is the most suitable nidus for their growth, but agreed with Pfeiffer in believing that the

chief symptoms are produced by toxins resident in the bodies of the bacilli. He made control experiments by injecting other organisms, and also by injecting inert substances into the cerebral tissue.

The evidence, accordingly, that the influenza bacillus is the cause of the disease rests chiefly on the well-established fact that it is always present in the secretions of the respiratory tract in true cases of influenza, and often in very large numbers. The observed relationships of the organism to lesions in the lungs and elsewhere leave no room for doubt that it is possessed of pathogenic properties, but we cannot yet maintain that its causal relationship to epidemic influenza is absolutely established.

Methods of Examination. — (*a*) *Microscopic.* — A portion of the greenish-yellow purulent material which often occurs in little round masses in the sputum should be selected, and film preparations should be made in the usual way. Films are best stained by Ziehl-Neelsen carbol-fuchsin diluted with ten parts of water, the films being stained for ten minutes at least. In sections of the tissues, such as the lungs, the bacilli are best brought out, according to Pfeiffer, by staining with the same solution as above for half an hour. The sections are then placed in alcohol containing a few drops of acetic acid, in which they are dehydrated and slightly decolorised at the same time. They should be allowed to remain till they have a moderately light colour, the time varying according to their appearance. They are then washed in pure alcohol, cleared in xylol, and afterwards mounted in balsam.

(*b*) *Cultures.*—A suitable portion of the greenish-yellow material having been selected from the sputum, it should be washed well in several changes of sterilised water. A portion should then be taken on a platinum needle, and successive strokes made on the surface of blood-agar tubes. The tubes should then be incubated at 37° C., when the transparent colonies of the influenza bacillus will appear, usually within twenty-four hours. These should give a negative result on inoculation on ordinary agar media.

Whooping-cough.

Up to the year 1906, the chief result of bacteriological observations, of which those of Spengler, Krause and Jochmann, and Davis may be mentioned, had been to demonstrate the very frequent presence of minute influenza-like and hæmophilic bacilli in the sputum and also in the lesions in this disease. In the year mentioned, however, Bordet and Gengou published an account of another minute organism, and brought forward certain facts which gave strong support to its etiological relationship. A short description of this bacillus may accordingly be given.

Characters of the Bacillus (Bordet-Gengou).—The organism, as seen, for example, in the sputum, occurs in the form of

minute oval rods scarcely larger than the influenza bacillus. They stain rather faintly with ordinary stains, and their margin and extremities are often more deeply coloured than the centre, which may appear as an uncoloured spot; they are Gram-negative and do not form spores. In cultures they present the same characters and are less pleomorphous than the influenza bacillus (Fig. 144). They are specially numerous at the beginning of the disease, and they may be found in large numbers in almost pure culture in the opaque whitish sputum expectorated from the bronchi; as the disease advances they become scanty, and may disappear when the symptoms of the disease are still prominent. The bacillus has not been found in the blood, unless as an agonal phenomenon (Klimenko). Bordet and Gengou succeeded in obtaining pure cultures on the blood-agar medium described on p. 45, and this was found to be the most suitable of all the media tried. In the first cultures growth is very scanty and may be invisible, but later it becomes much more abundant, and sub-cultures may also be readily made on ordinary serum-agar media. As compared with that of the influenza bacillus, growth is thicker and less transparent and the margins are more sharply marked off; the presence of hæmoglobin, though favouring the growth, is not so essential as in the case of the latter organism. The organism is a strict aerobe, and in the case of cultures in fluid media, *e.g.*, serum bouillon, the tubes ought to be placed in a sloped position, in order to expose a greater surface to the air. Bordet and Gengou completely confirmed the observations mentioned above as to the very frequent, almost constant, presence of influenza-like

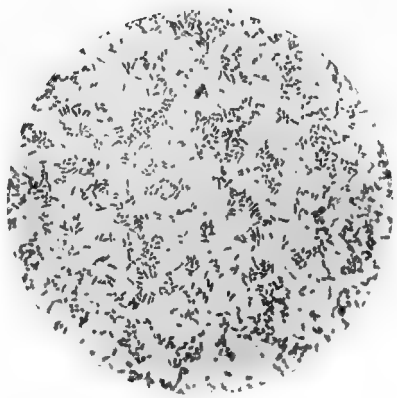

FIG. 144.[1]—Film preparation from a twenty-four hours' culture of the bacillus of whooping-cough. (Bordet-Gengou.) Stained with carbol-fuchsin. × 1000.

[1] We are indebted to Dr. Bordet for the culture from which this preparation was made.

bacilli. They obtained growths of these organisms, and on comparing them with their own bacillus found that distinct cultural differences could be made out. The most marked distinctions were, however, obtained on studying the serum reactions of convalescents from the disease. They found that in many cases, though not invariably, such sera agglutinated their bacillus, but none of the influenza-like organisms. The most important result, however, was that in every case examined the serum of convalescents gave the deviation of complement reaction very markedly with the whooping-cough bacillus, but with none of the others. This means, of course, that a true anti-substance to the bacillus (immune-body or *substance sensibilisatrice*) was present in the serum, and points to a true infection with the organism (p. 127). The results of the application of the test to adults suffering from bronchial irritation have been to show that they more frequently suffer from whooping-cough infection than was formerly supposed, the paroxysmal stage being often absent.

Pathogenic Effects.—The general results obtained by Bordet and Gengou were that the ordinarily used animals were not susceptible to true infection with the bacillus, but that it contained a powerfully acting endotoxin, which produced both local and general effects. The injection of a small quantity of the bacillus into the eye of a rabbit produced a local necrosis, with little inflammatory change, and the introduction of dead, as well as living, cultures into guinea-pigs caused death from toxic action, there being hæmorrhagic œdema locally, and hæmorrhages and necrotic foci in organs. Similar results were obtained with an endotoxin prepared according to Besredka's method. They advanced the view that the bacillus is present in large numbers at the beginning of the disease, and inflicts some local damage on the bronchial tubes which may persist after the disappearance of the bacillus and keep up the irritation. It was not found possible to obtain an antitoxin to this toxin. Very important results have, however, been since obtained by Klimenko, who succeeded in infecting monkeys and young dogs by intratracheal injection of pure cultures of the bacillus. After a period of incubation, there occurred an illness in which symptoms of pulmonary irritation and irregular pyrexia were outstanding features. Usually, in the case of the dogs, a fatal result followed after two or three weeks, and *post mortem* there were found symptoms of catarrh of the respiratory tract and sometimes patches of broncho-pneumonia, from which the bacillus could be recovered in pure culture. The serum of the infected

animals gave the deviation of complement reaction. A specially interesting fact is that a number of healthy young dogs contracted the disease by contact with the inoculated. Fraenkel also obtained positive results, closely similar to those of Klimenko, on inoculation with pure cultures of the bacillus.

The results of Bordet and Gengou have received general confirmation, although it is to be noted that Fraenkel and also Wollstein failed to obtain the deviation of complement reaction with the serum of convalescents. Bordet and Gengou have inquired into this discrepancy in the case of the former, and find that it depends on the nature of the culture medium used. At present it is not justifiable to make a definite pronouncement on the subject. We can only say that Bordet and Gengou have made out a strong case for the etiological relationship of their bacillus, and that their observations have been confirmed by those of others.

Methods of Examination.—A portion of sputum expectorated during a paroxysm of coughing should be obtained at as early as possible a stage of the disease; film preparations should be made in the usual way and stained by carbol-thionin or carbol-methylene-blue. If the characteristic bacilli largely preponderate, tubes of the Bordet-Gengou medium may then be inoculated and incubated. If there are numerous colonies of other organisms in the tubes, a portion of the intervening agar should be scraped with a needle and fresh tubes inoculated. As already said, growth is at first very scanty but becomes more luxuriant in sub-cultures. On pure cultures being obtained, the deviation of complement test is to be applied by the method described (p. 127).

Plague.

The bacillus of Oriental plague or bubonic pest was discovered independently by Kitasato and by Yersin during the epidemic at Hong-Kong in 1894. They cultivated the organism from a large number of cases of plague, and reproduced the disease in susceptible animals by inoculation of pure cultures. It is to be noted that during an epidemic of plague, sometimes even preceding it, a high mortality has been observed amongst certain animals, especially rats and mice, and that from the bodies of these animals found dead in the plague-stricken district, the same bacillus was obtained by Kitasato and also by Yersin.

Bacillus of Plague.—*Microscopical Characters.*—As seen in the affected glands or buboes in this disease, the bacilli are small oval rods, somewhat shorter than the typhoid bacillus, and about the same thickness (Fig. 145), though considerable variations in size occur. They have rounded ends, and in

stained preparations a portion in the middle of the bacillus is often left uncoloured, giving the so-called "polar staining." In films from the tissues they are found scattered amongst the cells, for the most part lying singly, though pairs are also seen. On the other hand, in cultures in fluids, *e.g.*, bouillon, they grow chiefly in chains, sometimes of considerable length, the form known as a streptobacillus resulting (Fig. 147). In young agar

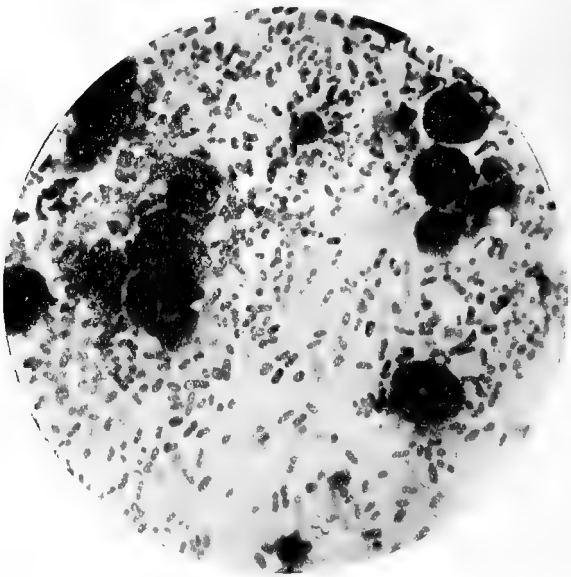

FIG. 145.—Film preparation from a plague bubo, showing enormous numbers of bacilli, most of which show well-marked bipolar staining. Stained with weak gentian-violet. ×1000.

cultures the bacilli show greater variation in size, and polar staining is less marked than in the tissues: sometimes forms of considerable length are present. After a time involution forms appear, especially when the surface of the agar is dry; but the formation of these is much more rapid and more marked when 2 to 5 per cent. of sodium chloride is added to the medium, constituting the so-called "salt agar" (Hankin and Leumann). On this medium, especially with the higher percentage, the involution forms assume a great size and a

striking variety of shapes, large globular, oval, or pyriform bodies resulting (Fig. 148); with about 2 per cent. sodium chloride, after twenty-four hours' incubation, the most striking feature is a general enlargement of all the bacilli. Sometimes in the tissues they are seen to be surrounded by an unstained capsule, though this appearance is by no means common. They do not form spores, and are non-motile. They stain readily with the basic aniline stains, but are Gram-negative.

FIG. 146.—Bacillus of plague from a young culture on agar. Stained with weak carbol-fuchsin. ×1000.

Cultivation. — From the affected glands, etc., the bacillus can readily be cultivated on the ordinary media. It grows best at the temperature of the body, though growth occurs as low as 18° C. On agar and on blood serum the colonies are whitish circular discs of somewhat transparent appearance, and smooth, shining surface. When examined with a lens, their borders appear slightly wavy. In stroke cultures on agar there forms a continuous line of growth with the same appearance, showing partly separated colonies at its margins. When agar cultures are kept at the room temperature, some of the colonies may show a more luxuriant growth with more opaque appearance than the rest of the growth, the appearance in fact being often such as to suggest

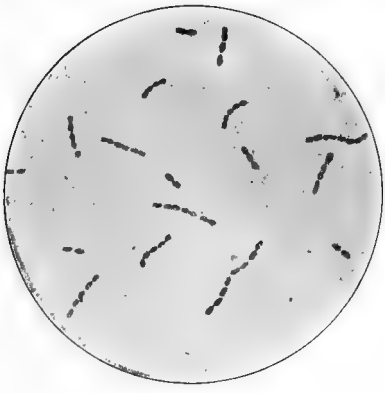

FIG. 147.—Bacillus of plague in chains showing polar staining. From a young culture in bouillon. Stained with thionin-blue. ×1000.

the presence of impurities in the cultures. In stab cultures in peptone gelatin, growth takes place along the needle track as a white line, composed of small spherical colonies. On the surface of the gelatin a thin, semi-transparent layer may be formed, which is usually restricted to the region of puncture, though sometimes it may spread to the wall of the tube; sometimes, however, there is practically no surface growth. There is no liquefaction of the medium. In bouillon the growth usually forms a slightly granular or powdery deposit at the foot and sides of the flask, somewhat resembling that of a streptococcus. If oil or melted butter is added to the bouillon so that drops float on the surface, then a striking mode of growth may result, to which the term "stalactite" has been applied. This consists in the growth starting from the under surface of the fat globules and extending downwards in the form of pendulous, string-like masses. These masses are exceedingly delicate, and readily break off on the slightest shaking of the flask; accordingly during their formation the culture must be kept absolutely at rest. This manner of growth constitutes an important but not absolutely specific character of the organism; unfortunately it is not supplied by all strains of the organism, and varies from time to time with the same strain. The organism flourishes best in an abundant supply of oxygen; in strictly anaerobic conditions almost no growth takes place.

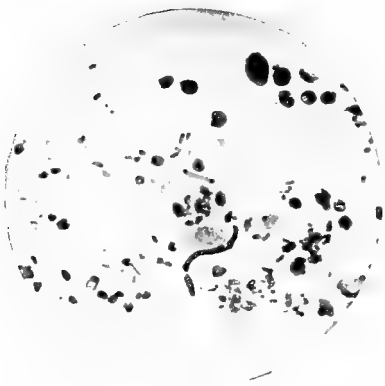

FIG. 148.—Culture of the bacillus of plague on 4 per cent. salt agar, showing involution forms of great variety of size and shape. See also Plate IV., Fig. 17. Stained with carbol-thionin-blue. ×1000.

The organism in its powers of resistance corresponds with other spore-free bacilli, and is readily killed by heat, an exposure for an hour at 58° C. being fatal. On the other hand, it has remarkable powers of resistance against cold; it has been exposed to a temperature several degrees below freezing-point without being killed. Experiments on the effects of drying have given somewhat diverse results, but as a rule the organism has been

found to be dead after being dried for from six to eight days, though sometimes it has survived the process for a longer period; exposure to direct sunlight for three or four hours kills it. The general result has been to show that the organism does not remain alive in natural conditions for long outside the animal body.

Anatomical Changes and Distribution of Bacilli.—The disease occurs in several forms, the *bubonic* and the *pulmonary* being the best recognised; to these may be added the *septicæmic*. The most striking feature in the *bubonic* form is the affection of the lymphatic glands, which undergo intense inflammatory swelling, attended with hæmorrhage, and generally ending in a greater or less degree of necrotic softening if the patient lives long enough. The connective tissue around the glands is similarly affected. The bubo is thus usually formed by a collection of enlarged glands fused by the inflammatory swelling. True suppuration is rare. Usually one group of glands is affected first, constituting the primary bubo—in the great majority the inguinal or the axillary glands—and afterwards other groups may become involved, though to a much less extent. Along with these changes there is great swelling of the spleen, and often intense cloudy swelling of the cells of the kidneys, liver, and other organs. There may also occur secondary areas of hæmorrhage and necrosis, chiefly in the lungs, liver, and spleen. The bacilli occur in enormous numbers in the swollen glands, being often so numerous that a film preparation made from a scraping almost resembles a pure culture (Fig. 145). In sections of the glands in the earlier stages the bacilli are found to form dense masses in the lymph paths and sinuses (Fig. 149), often forming an injection of them; they may also be seen growing as a fine reticulum between the cells of the lymphoid tissue. At a later period, when disorganisation of the gland has occurred, they become irregularly mixed with the cellular elements. Later still they gradually disappear, and when necrosis is well advanced it may be impossible to find any —a point of importance in connection with diagnosis. In the spleen they may be very numerous or they may be scanty, according to the amount of blood infection which has occurred; in the secondary lesions mentioned they are often abundant. In the *pulmonary* form the lesion is the well-recognised "plague pneumonia." This is of broncho-pneumonic type, though large areas may be formed by confluence of the consolidated patches, and the inflammatory process is usually attended by much hæmorrhage; the bronchial glands show inflammatory swelling.

Clinically there is usually a fairly abundant frothy sputum often tinted with blood, and in it the bacilli may be found in large numbers. Sometimes, however, cough and expectoration may be absent. The disease in this form is said to be invariably fatal; it is also extremely infective. In the *septicæmic* form proper there is no primary bubo discoverable, though there is almost always slight general enlargement of lymphatic glands;

FIG. 149.—Section of a human lymphatic gland in plague, showing the injection of the lymph paths and sinuses with masses of plague bacilli—seen as black areas.
Stained with carbol-thionin-blue. × 50.

here also the disease is of specially grave character. A bubonic case may, however, terminate with septicæmia; in fact, all intermediate forms occur. An *intestinal* form with widespread affection of the mesenteric glands has been described, but it is exceedingly rare—so much so that many observers with extensive experience have doubted its occurrence. In the various forms of the disease the bacilli occur also in the blood, in which they may be found during life by microscopic examination, chiefly,

however, just before death in very severe and rapidly fatal cases. The examination of the blood by means of cultivation experiments is, however, a much more reliable procedure. For this purpose about 5 c.c. of blood may be withdrawn from a vein and distributed in flasks of bouillon (p. 70). It may be said from the results of different investigators that the bacillus may be obtained by culture in fully 50 per cent. of the cases, though the number will necessarily vary in different epidemics. The Advisory Committee, appointed by the Secretary of State for India in 1905, found that in some septicæmic cases the bacilli may be present in the blood in large numbers, two, or even three, days before death, though this is exceptional.

The above types of the disease are usually classified together under the heading *pestis major*, but there also occur mild forms to which the term *pestis minor* is applied. In these latter there may be a moderate degree of swelling of a group of glands, attended with some pyrexia and general malaise, or there may be little more than slight discomfort. Between such and the graver types, cases of all degrees of severity are met with.

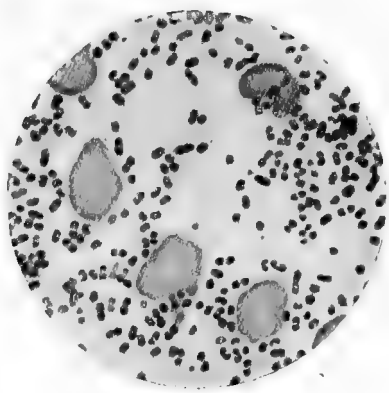

FIG. 150.—Film preparation of spleen of rat after inoculation with the bacillus of plague, showing numerous bacilli, most of which are somewhat plump. Stained with carbol-thionin-blue. ×1000.

Experimental Inoculation.—Mice, guinea-pigs, rats, and rabbits are susceptible to inoculation, the two former being on the whole most suitable for experimental purposes. After subcutaneous injection there occurs a local inflammatory œdema, which is followed by inflammatory swelling of the corresponding lymphatic glands, and thereafter by a general infection. The lesions in the lymphatic glands correspond in their main characters with those in the human subject, although usually at the time of death they have not reached a stage so advanced. By this method of inoculation mice usually die in 1 to 3 days, guinea-pigs and rats in 2 to 5 days, and rabbits in 4 to 7 days. *Post mortem* the chief changes, in addition to the glandular

enlargement, are congestion of internal organs, sometimes with hæmorrhages, and enlargement of the spleen; the bacilli are numerous in the lymphatic glands and usually in the spleen (Fig. 150), and also, though in somewhat less degree, throughout the blood. Infection can also be produced by smearing the material on the conjunctiva or mucous membrane of the nose, and this method of inoculation has been successfully applied in cases where the plague bacilli are present along with other virulent organisms, *e.g.*, in sputum along with pneumococci. Rats and mice can also be infected by feeding either with pure cultures or with pieces of organs from cases of the disease, though in this case infection probably takes place through the mucous membrane of the mouth and adjacent parts, and only to a limited extent, if at all, by the alimentary canal. Monkeys also are highly susceptible to infection, and it has been shown in the case of these animals that when inoculation is made on the skin surface, for example, by means of a spine charged with the bacillus, the glands in relation to the part may show the characteristic lesion and a fatal result may follow without there being any noticeable lesion at the primary seat. This fact throws important light on infection by the skin in the human subject.

Paths and Mode of Infection.—Plague bacilli may enter the system by the skin surface through small wounds, cracks, abrasions, etc., and in such cases there is usually no reaction at the site of entrance. This last fact is in accordance with what has been stated above with regard to experiments on monkeys. The path of infection is shown by the primary buboes, which are usually in the glands through which the skin is drained, those in the groin being the commonest site. Absolute proof of the possibility of infection by the skin is supplied by several cases in which the disease has been acquired at post-mortem examinations; in the majority of these the lesions of the skin surface were of trifling nature, and there was no local reaction at the site of inoculation. It may now, however, be regarded as established that the ordinary mode of skin infection is by means of the bites of fleas containing the bacilli. It had previously been shown that when fleas were allowed to feed on animals suffering from plague, plague bacilli might be found for some time afterwards in the stomach, and some observers, for example Simond, had succeeded in transmitting the disease to other animals by means of the infected insects. Most observers, however, had obtained negative results, and it was only by the work of the Advisory Committee

referred to above,[1] that the importance of this means of infection was established. By carefully planned experiments, the Committee showed that the disease could be transmitted from a plague rat to a healthy rat, kept in adjacent cages, when fleas were present; whereas this did not occur when means were taken to prevent the access of fleas, though the facilities for aerial infection were the same. The disease can also be produced by fleas removed from plague rats and transferred directly to healthy animals, success having been obtained in fully 50 per cent. of experiments of this kind. When plague-infected guinea-pigs are placed amongst healthy guinea-pigs, comparatively few of the latter acquire the disease when fleas are absent or scanty; whereas all of them may die of plague when fleas are numerous. This result demonstrates the comparatively small part played by direct contact, even when of a close character. Important results were also obtained with regard to the mode of infection in houses where there had been cases of plague. It was found possible to produce the disease in susceptible animals by means of fleas taken from rats in plague houses. When animals were placed in plague houses and efficiently protected from fleas they remained healthy; whereas they acquired the disease when the cages were free to the access of fleas in the neighbourhood.

The following are some of the experiments which were conducted: A series of six huts were built which only differed in the structure of their roofs. In two the roofs were made of ordinary native tiles in which rats freely lodge; in two others, flat tiles were used in which rats live, but in which they have not such facilities for movement as in the first set, and in the third pair the roof was formed of corrugated iron. Under the roof in each case was placed a wire diaphragm which prevented rats or their droppings having access to the hut, but which would not prevent fleas falling down on to the floor of the hut. The huts were left a sufficient time to become infected with rats, and then on the floor in each case healthy guinea-pigs mixed with guinea-pigs artificially infected with plague were allowed to run about together. In the first two sets of huts to which fleas had access the healthy guinea-pigs contracted plague, while in the third set they remained unaffected, though they were freely liable to contamination by contact with the bodies and excreta of the diseased animals. In the third set of huts no infection took place as long as fleas were excluded, but when accidentally these insects obtained admission, then infection of the uninoculated animals commenced. Other experiments were also performed. In one case healthy guinea-pigs were suspended in a cage two inches above a floor on which infected and flea-infested animals were running about. Infection occurred in the cage, but if the latter were suspended at a distance above the floor higher than a flea could jump, then no infection took place. Again,

[1] See *Journal of Hygiene*, vols. vi.–x.

in a hut in which guinea-pigs had died of plague, and which contained infected fleas, two cages were placed, each containing a monkey. One cage was surrounded by a zone of sticky material broader than the jump of a flea, another was left without this protection. The monkey in the former cage remained unaffected, but the other monkey contracted plague.

Other experiments showed that when plague bacilli were placed on the floors of houses, they died off in a comparatively short period of time. After forty-eight hours it was not found possible to reproduce plague by inoculation with material from floors which had been grossly contaminated with cultures of the bacillus. Afterwards, however, animals placed in such a house might become infected by means of fleas. In all these experiments the common rat-flea of India—*Pulex cheopis* (Rothschild)—was used, but it has been shown that this flea also infests and bites the human subject. Recent observations show that not only is plague transferable by means of fleas, but that this is practically the only method obtaining in natural conditions, with the exception that rats may become infected by eating the carcases of other animals containing large numbers of plague bacilli. It is improbable from the experiments made that bubonic plague is transmitted by direct contact even when of a close nature; in fact, it has been shown that plague-infected guinea-pigs may suckle their young without the latter acquiring the disease. *The general results show that in the bubonic type direct infection by dust and other material through small lesions of the skin plays a comparatively trifling part in the spread of the disease, fleas apparently being in nearly all cases the carriers of infection.*

The later work of the Committee supplied information of the highest value with regard to the epidemiology of the disease; it showed, in short, that plague in its epidemic form is dependent on the epizootic among rats, and with regard to this some further facts may be given. Plague in Bombay occurs in two chief species of rats, the *mus rattus*, the black house-rat, and *mus decumanus*, the grey rat of the sewers. The former, owing to its presence in dwelling-houses, is chiefly responsible for the transmission of the disease to man; while the latter, on account of the large number of fleas which infest it, is of special importance in maintaining the disease from season to season. The year may be divided into two portions—an epizootic season, from December to May inclusive, and a non-epizootic, from June to November. During the latter period there are few cases of plague in rats on account of fleas

being scanty; especially is this so in the case of *mus rattus*. In fact, in certain villages where this species alone is present, the disease may actually die out at the end of the epizootic season, and accordingly when plague reappears in these places this is due to a fresh importation—a fact of great practical importance. A fresh epizootic first affects chiefly *mus decumanus*, and a little later spreads to *mus rattus*, while a little later still the disease attacks the human subject in the epidemic form; in each case fleas form the vehicle of transmission, and an interval of from ten to fourteen days intervenes between the outbreak of the epizootic and that of the epidemic. The proportion of cases of plague in *mus decumanus* is much higher than in *mus rattus*, for the reason mentioned. It has been further shown that the bacilli flourish in the stomach of the flea and are passed in a virulent condition in the fæces, that a large proportion of the fleas removed from plague-infected rats contain plague bacilli, and that the fleas may remain infective for a considerable number of days, sometimes for a fortnight. The subsidence of plague when the mean temperature rises above a certain level (about 80° F.) is probably in part, at least, due to the fact that the bacilli disappear much more rapidly from the alimentary tract of fleas at the higher temperatures; in accordance with this, experimental transmission of the disease to animals by means of fleas is more frequently successful at lower temperatures. C. J. Martin has shown that infection occurs by regurgitation of infected blood from the stomach of the flea during the act of biting, the proventriculus being sometimes blocked by a mass of plague bacilli. The possibility of infection by contamination of the skin by the excrement of fleas containing the bacilli, however, cannot be excluded.

As regards the dying out of epidemics, some interesting facts have been brought forward by Liston. He and his co-workers have shown that rats taken from different towns vary greatly in their susceptibility to inoculation with plague bacilli, and that immunity is most marked in the rats from the towns which have suffered most severely from plague. This relative immunity appears to be due to the survival of the more resistant animals, and holds also with regard to their young. The diminution of plague amongst rats, and thus the subsidence of an epidemic, accordingly depends on the killing off of the more susceptible animals.

In primary plague pneumonia, from a consideration of the anatomical changes and the clinical facts, the disease may be said to be produced by the direct passage of the bacilli into the

respiratory passages by inhalation. And accordingly a case of plague pneumonia is of great infectivity in producing other cases of plague pneumonia. Small epidemics of plague pneumonia break out from time to time, but in 1911 an extensive epidemic occurred in Manchuria leading to 50,000 deaths in six months. In this epidemic, direct infection from patient to patient was clearly shown, and rats were not concerned in the spread. Plague pneumonia appears to occur first of all as a complication in a bubonic case, and there is no evidence that the bacilli differ in virulence in the two conditions.

Toxins, Immunity, etc.—As is the case with most organisms which extensively invade the tissues, the toxins in plague cultures are chiefly contained in the bodies of the bacteria. Injection of dead cultures in animals produces distinctly toxic effects; *post mortem*, hæmorrhage in the mucous membrane of the stomach, areas of necrosis in the liver and at the site of inoculation, may be present. The toxic substances are comparatively resistant to heat, being unaffected by an exposure to 65° C. for an hour. By the injection of dead cultures in suitable doses, a certain degree of immunity against the living virulent bacilli is obtained, and, as first shown by Yersin, Calmette, and Borrel, the serum of such immunised animals confers a degree of protection on small animals such as mice. On these facts the principles of preventive inoculation and serum treatment, presently to be described, depend. It may also be mentioned that the filtrate of a plague culture possesses a very slight toxic action, and the Indian Plague Commission found that such a filtrate has practically no effect in the direction of conferring immunity.

1. *Preventive Inoculation—Haffkine's Method.*—To prepare the preventive fluid, cultures are made in flasks of bouillon with drops of oil on the surface (in India Haffkine employed a medium prepared by digesting goat's flesh with hydrochloric acid at 140° C. and afterwards neutralising with caustic soda). In such cultures stalactite growths (*vide supra*) form, and the flasks are shaken every few days so as to break up the stalactites and induce fresh crops. The flasks are kept at a temperature of about 25° C., and growth is allowed to proceed for about six weeks. At the end of this time sterilisation is effected by exposing the contents of the flasks to 65° C. for an hour; thereafter carbolic acid is added in the proportion of ·5 per cent. The contents are well shaken to diffuse thoroughly the sediment in the fluid, and are then distributed in small sterilised bottles for use. The preventive fluid thus contains both the dead bodies of the bacilli and any toxins which may be in solution.

It is administered by subcutaneous injection in the dose prescribed. Usually only one injection is made, sometimes two, though the latter procedure does not appear to have any advantage. The method has been systematically tested by inoculating a certain proportion of the inhabitants of districts exposed to infection, leaving others uninoculated, and then observing the proportion of cases of disease and the mortality amongst the two classes. The results of inoculation have been distinctly satisfactory. For although absolute protection is not afforded by inoculation, both the proportion of cases of plague and the percentage mortality amongst these cases have been considerably smaller in the inoculated as compared with the uninoculated. Protection is not established till some days after inoculation, and lasts for a considerable number of weeks, possibly for several months (Bannerman). In the Punjab during the season 1902–3 the case incidence among the inoculated was 1·8 per cent., among the uninoculated 7·7 per cent., while the case mortality was 23·9 and 60·1 per cent. respectively in the two classes, the statistics being taken from villages where 10 per cent. of the population and upwards had been inoculated.

2. *Anti-plague Sera.*—Of these, two have been used as therapeutic agents, namely, that of Yersin and that of Lustig. Yersin's serum is prepared by injections of increasing doses of plague bacilli into the horse. In the early stages of immunisation dead bacilli are injected subcutaneously, thereafter into the veins, and, finally, living bacilli are injected intravenously. After a suitable time blood is drawn off and the serum is preserved in the usual way. Of this serum 10 to 20 c.c. are used, and injections are usually repeated on subsequent days. Lustig's serum is prepared by injecting a horse with repeated and increasing doses of a substance derived from the bodies of plague bacilli, probably in great part nucleo-proteid. Masses of growth are obtained from the surface of agar cultures, and are broken up and dissolved in a 1 per cent. solution of caustic potash. The solution is then made slightly acid by hydrochloric acid, when a bulky precipitate forms; this is collected on a filter and dried. For use, a weighed amount is dissolved in a weak solution of carbonate of soda and then injected. The serum is obtained from the animal in the usual way. Extensive observations with both of these sera show that neither of them can be considered a powerful remedy in cases of plague, though in certain instances distinctly favourable results have been recorded. The Indian Commission, however, came to the conclusion "that, on the whole, a certain amount of advantage accrued to the patients in cases both of those injected with Yersin's serum and of those injected with Lustig's serum." It may also be mentioned that the Commission found, as the result of experiments, that Yersin's serum modified favourably the course of the disease in animals, whereas Lustig's serum had no such effect.

3. *Serum Diagnosis.*—Specific agglutinins may appear in the blood of patients suffering from plague, as also they do in the case of animals

immunised against the plague bacillus. It is to be noted, however, that in clinical cases the reaction is not invariably present, the potency of the serum is not of high order, and the carrying out of the test is complicated by the natural tendency of the bacilli to cohere in clumps. For the last reason the macroscopic (sedimentation) method is to be preferred to the microscopic (p. 116). A suspension of plague bacilli is made by breaking up a young agar culture in ·75 per cent. sodium chloride solution ; the larger flocculi of growth are allowed to settle, and the fine, supernatant emulsion is employed in the usual way. According to the results of the German Plague Commission and the observations of Cairns, made during the Glasgow epidemic, it may be said that the reaction is best obtained with dilutions of the serum of from 1 : 10 to 1 : 50. Cairns found that the date of its appearance is about a week after the onset of illness, and that it usually increases till about the end of the sixth week, thereafter fading off. It is most marked in severe cases characterised by an early and favourable crisis, less marked in severe cases ultimately proving fatal, whilst in very mild cases it is feeble or may be absent. The method, if carefully applied, may be of service under certain conditions ; but it will be seen that its use as a means of diagnosis is restricted.

Methods of Diagnosis.—Where a bubo is present a little of the juice may be obtained by plunging a sterile hypodermic needle into the swelling. The fluid is then to be examined microscopically, and cultures on agar or blood serum should be made by the successive stroke method. The cultural and morphological characters are then to be investigated, the most important being the involution forms on salt agar and the stalactite growth in bouillon, though the latter may not always be obtained with the plague bacillus : the pathogenic properties should also be studied, the guinea-pig being on the whole most suitable for subcutaneous inoculation. In many cases a diagnosis may be made by microscopic examination alone, as in no known condition other than plague do bacilli with the morphological characters of the plague bacillus occur in large numbers in the lymphatic glands. The organism may be obtained in culture from the blood in a considerable proportion of cases by withdrawing a few cubic centimetres and proceeding in the usual manner. On the occurrence of the first suspected case, every care to exclude possibility of doubt should be used before a positive opinion is given.

In a case of suspected plague pneumonia, in addition to microscopic examination of the sputum, the above cultural methods along with animal inoculation with the sputum should be carried out ; subcutaneous injection in the guinea-pig and smearing the nasal mucous membrane of the rat may be recommended. Here a positive diagnosis should not be attempted by microscopic examination alone, especially in a plague-free district, as bacilli morphologically resembling the plague organism may occur in the sputum in other conditions.

Malta Fever.

Synonyms—Mediterranean Fever : Rock Fever of Gibraltar : Neapolitan Fever, etc.

This disease is of common occurrence along the shores of the Mediterranean and in its islands. Since its bacteriology has

been worked out, it has been found to occur also in India, China, South Africa, and in some parts of North and South America, its distribution being much wider than was formerly supposed. Although from its symptomatology and pathological anatomy it had been recognised as a distinct affection, and was known under various names, its precise etiology was unknown till the publication of the researches of Surg.-General Bruce in 1887. From the spleen of patients dead of the disease he cultivated a characteristic organism, now known as the *Micrococcus melitensis*, and by means of inoculation experiments established its causal relationship to the disease. Wright and Semple applied the agglutination test to the diagnosis of the disease, and in 1904 the mode of spread of the disease was fully studied by a Commission, whose work demonstrated that goat's milk is the chief means of infection.

The duration of the disease is usually long—often two or three months, though shorter and much longer periods are met with. Its course is very variable, the fever being of the continued type with irregular remissions. In addition to the usual symptoms of pyrexia, there occur profuse perspiration, pains and sometimes swellings in the joints, occasionally orchitis, whilst constipation is usually a marked feature. The mortality is low—about 2 per cent. (Bruce).

In fatal cases the most striking post-mortem change is in the spleen. This organ is enlarged, often weighing slightly over a pound, and in a condition of acute congestion; the pulp is soft and may be diffluent, and the Malpighian bodies are swollen and indistinct. In the other organs the chief change is cloudy swelling; in the kidneys there may be in addition glomerular nephritis. The lymphoid tissue of the intestines shows none of the changes characteristic of typhoid fever.

Micrococcus melitensis.—This is a small, rounded, or slightly oval organism about ·4 μ in diameter, which is specially abundant in the spleen. It usually occurs singly or in pairs, but in cultures short chains are also met with (Fig. 151). (Durham has shown that in old cultures kept at the room temperature bacillary forms appear, and we have noticed indications of such in comparatively young cultures; the usual form is, however, that of a coccus.) It stains fairly readily with the ordinary basic aniline stains, but loses the stain in Gram's method. It is generally said to be a non-motile organism. Gordon, however, is of a contrary opinion, and has demonstrated that it possesses from one to four flagella, which, however, are difficult to stain. In the spleen of a patient dead of the disease it

occurs irregularly scattered through the congested pulp; it may also be found in small numbers *post mortem* in the capillaries of various organs. It may be cultivated from the blood during life in a considerable proportion of cases; for this purpose 5 to 10 c.c. of blood should be withdrawn from a vein and distributed in small flasks of bouillon. The micrococcus was found by the members of the Commission in the urine of Malta fever patients in 10 per cent. of the cases examined; it was sometimes scanty, but sometimes present in large numbers. It has also occasionally been obtained from the fæces.

Cultivation.—This can usually be effected by making stroke cultures on agar tubes from the spleen pulp and incubating at 37° C. The colonies, which are usually not visible before the third or fourth day, appear as small round discs, slightly raised and of somewhat transparent appearance. The maximum size—2 to 3 mm. in diameter—is reached about the ninth day; at this period by reflected light they appear pearly white, while by transmitted light they have a yellowish tint in the centre, bluish-white at the periphery. A stroke culture shows a layer of growth of similar appearance with somewhat serrated margins. The optimum temperature is 37° C., but growth still occurs down to about 20° C. On gelatin at summer temperature growth is extremely slow—after two or three weeks, in a puncture culture, there is a delicate line of growth along the needle track and a small flat expansion of growth on the surface. There is no liquefaction of the medium. In bouillon there occurs a general turbidity with flocculent deposit at the bottom; on the surface there is no formation of a pellicle. The reaction of the media ought to be very faintly alkaline, as marked alkalinity interferes with the growth; a reaction of +10 (p. 34) has been found very suitable. On potatoes no visible growth takes place even at the body temperature,

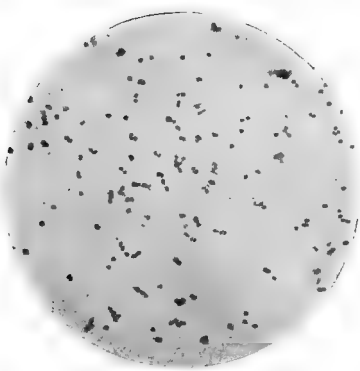

FIG. 151.—Micrococcus melitensis, from a two days' culture on agar at 37° C. Stained with fuchsin. ×1000.

though the organism multiplies to a certain extent. Outside the body the organism has considerable powers of vitality, as it has been found to survive in a dry condition in dust and clothing for a period of two months.

Relations to the Disease.—There is in the first place ample evidence, from examination of the spleen, both *post mortem* and during life, that this organism is always present in the disease. The experiments of Bruce and Hughes first showed that by inoculation with even comparatively small doses of pure cultures the disease could be produced in monkeys, sometimes with a fatal result. And it has now been fully established that inoculation with the minutest amount of culture, even by scarification, leads to infection both in monkeys and in the human subject.

Rabbits, guinea-pigs, and mice are, as a rule, insusceptible to inoculation by the ordinary method, though some strains may produce pathogenic effects. Durham, by using the intracerebral method of inoculation, however, succeeded in raising the virulence, so that the organism is capable of producing in guinea-pigs on intraperitoneal injection illness with sometimes a fatal result many weeks afterwards. Eyre also, by increasing the virulence by intracerebral inoculation, was able to produce infection in various animals, especially on intravenous injection.

Mode of Spread of the Disease.—The work of the 1904 Commission resulted in establishing facts of the highest importance with regard to the spread of the disease. In the course of investigations Zammitt found that the blood of many of the goats agglutinated the micrococcus melitensis, and Horrocks obtained cultures of the organism from the milk. Further observations showed that agglutination was given in the case of 50 per cent. of the goats in Malta, whilst the organism was present in the milk in 10 per cent. Sometimes the organism was present in enormous numbers, and in these cases the animal usually appeared poorly nourished, whilst the milk had a somewhat serous character. In other cases, however, it was found when the animals appeared healthy, and there was no physical or chemical change discoverable in the milk. It was also determined that the organism might be excreted for a period of two to three months before any notable change occurred in the milk. Agglutination is usually given by the milk of infected animals, and this property was always present when the micrococcus was found in the milk. It was, moreover, found that monkeys and goats could be readily infected by feeding them with milk containing the micrococcus, the disease being contracted by fully 80 per cent. of the monkeys used. It was therefore

rendered practically certain that the human subject was infected by means of such milk, and the result of preventive measures, by which milk was excluded as an article of dietary amongst the troops in Malta, has fully borne out this view. After such measures were instituted, the number of cases in the second half of 1906 fell to 11 per thousand, as contrasted with 47 per thousand in the corresponding part of the preceding year; cases now are relatively few. Various facts with regard to the epidemiology of the disease have thus been cleared up. For example, it is more prevalent in the summer months, when more milk is consumed; and there is a larger proportion of cases amongst those in good social position, the officers, for example, suffering more in proportion than the privates. Another interesting fact, pointed out by Horrocks, is that the disease has practically disappeared from Gibraltar since the practice of importing goats from Malta has stopped. The manner in which the disease spreads from goat to goat has not yet been satisfactorily determined. It has recently been found that the sheep may be the subject of infection and that the micrococcus may be excreted in its milk. It remains to be seen to what extent this obtains.

The work of the Commission, so far as it went, excluded other modes of infection than the ingestion of infected milk as being of practical importance; if the disease is conveyed by contact at all, this is only when the contact is of an intimate character, and even then it is probably of rare occurrence. Although numerous patients suffering from the disease come to England, there is no known case of fresh infection arising under natural conditions.

There is distinct evidence that the disease may be acquired by inoculation through small lesions in the skin, and this method is probably not infrequent amongst those who handle infected milk. It has been shown that the organism may remain alive in the bodies of mosquitoes for four or five days, and possibly these insects may occasionally be the means of carrying the disease; there is no evidence, however, that this takes place to any extent.

Agglutinative Action of Serum.—The blood serum of patients suffering from Malta fever possesses the power of agglutinating the micrococcus melitensis in a manner analogous to what has been described in the case of typhoid fever; here also dead cultures may be used. The reaction appears comparatively early, often about the fifth day, and may be present for a considerable time after recovery—sometimes for more than a year.

Distinct agglutination with a 1 : 30 dilution of the serum in half an hour may be taken as a positive reaction, sufficient for diagnosis. The reaction is, however, usually given by much higher dilutions, *e.g.*, 1 : 500, and even higher. It is to be noted that normal serum diluted 1 : 5 may produce some agglutination, and this property is said to be destroyed at 55° C., whereas the specific agglutinin is not affected. Some observers accordingly recommend that, in applying the test, the serum ought to be first heated to 55° C. As regards relation to prognosis, the observations of Birt and Lamb and of Bassett-Smith have given results analogous to those obtained in typhoid (p. 374).

The Commission found that vaccination with dead cultures of the micrococcus confers a certain degree of protection amongst those exposed to the disease. As a rule two injections were made, 200–300 million cocci being the dose of the first injection, and about 400 million the dose of the second. The use of vaccines has also been carried out in the treatment of the disease, but the observations are not sufficiently numerous to allow a definite statement to be made as to its value.

Methods of Diagnosis.—During life the readiest means of diagnosis is supplied by the agglutinative test just described (for technique, *vide* p. 116).

Cultures are most easily obtained from the spleen either during life or *post mortem*. Inoculate a number of agar tubes by successive strokes and incubate at 37° C. Film preparations should also be made from the spleen pulp and stained with carbol-thionin-blue or diluted carbol-fuchsin (1 : 10). Cultures may sometimes be obtained from the blood by the usual methods.

Great care must be exercised in working with cultures of the m. melitensis, as bacteriologists have become infected with the disease, apparently from such sources, in an unusually high proportion of instances as compared with other affections.

CHAPTER XX.

DISEASES DUE TO SPIROCHÆTES—THE RELAPSING FEVERS, SYPHILIS, AND FRAMBŒSIA.

THE diseases produced by spirochætes — spirilloses or spirochætoses—fall into two main groups, one represented by the human spirillar fevers and the corresponding affections of various animals, and the second having as its two chief members syphilis and yaws, though to the organisms of these diseases various spirochætes found in ulcerative and gangrenous conditions seem to be closely related. The members of the first group are essentially blood infections, and the organisms are in most, if not in all cases, transmitted by blood-sucking ecto-parasites; in the second group the organisms are primarily tissue-parasites, blood invasion when it occurs being a later phenomenon, and infection would appear to occur by direct contact. Infective jaundice, recently shown to be due to a spirochæte, occupies a somewhat intermediate position, as the organisms occur in the blood stream but tend to settle and flourish in certain organs. As regards general morphology, staining reactions, conditions of growth and culture, the various spirochætes present certain common characters, and, as already stated, it is still uncertain whether they are to be regarded as bacteria or as protozoa, though the balance of opinion is now distinctly in favour of the latter.

RELAPSING FEVERS AND AFRICAN TICK FEVER.

At a comparatively early date, namely in 1873, when practically nothing was known with regard to the production of disease by bacteria, a highly characteristic organism was discovered by Obermeier in the blood of patients suffering from relapsing fever. This organism is usually known as the *spirillum* or *spirochæte obermeieri*, or the *spirillum of relapsing fever*. He described its microscopical characters, and found

that its presence in the blood had a definite relation to the time of the fever, as the organism rapidly disappeared about the time of the crisis, and reappeared when a relapse occurred. His observations were fully confirmed, and his views as to its causal relationship to the disease have been established as correct.

Within recent years relapsing fever has been carefully studied in different parts of the world, and the relationships of the organisms have been the subject of much investigation and discussion. This question will be referred to again below. It has also been shown that the so-called "tick fever" prevalent in Africa is due to a spirochæte of closely similar character, and results of the highest importance have been established with regard to the part played by ticks in the transmission of the disease. As a matter of convenience, we shall give the chief facts regarding these diseases separately. It has also been shown that spirochætal diseases or "spirilloses," as they are called, are widespread amongst vertebrates; they have been described, for example, in geese by Sacharoff, in fowls by Marchoux and Salimbeni, in oxen and sheep by Theiler, and in bats by Nicolle and Comte, and it is interesting to note that in the case of the spirilloses of oxen and fowls the infection is transmissible by means of ticks.

Characters of the Spirochæte of Relapsing Fever.—The organisms as seen in the blood during the fever are delicate spiral filaments which have a length of from two to six times the diameter of a red blood corpuscle. They are, however, exceedingly thin, their thickness being much less than that of the cholera spirillum. They show several regular sharp curves or windings, of number varying according to the length of the organisms, and their extremities are finely pointed (Fig. 152). They are actively motile, and may be seen moving quickly across the microscopic field with a peculiar movement which is partly twisting and partly undulatory, and disturbing the blood corpuscles in their course. There are often to be seen in the spirals, portions which are thinner and less deeply stained than the rest, and which suggest the occurrence of transverse division. Fantham and Porter find that the sp. obermeieri and sp. duttoni multiply both by longitudinal and by transverse division, the former occurring especially during the onset of the fever.

They stain with watery solutions of the basic aniline dyes, though somewhat faintly, and are best coloured by the Romanowsky method or one of its modifications. When thus stained they usually have a uniform appearance throughout, or may be slightly granular at places, but they show no division

into short segments. They lose the stain in Gram's method. There is no evidence that they form spores.

Novy found that the spirochæte of American relapsing fever remained alive and virulent in defibrinated rats' blood for forty days. He also succeeded, by Levaditi's method, in obtaining cultures in collodion sacs containing rats' blood which were placed in the peritoneum of rats. Noguchi has succeeded in cultivating the spirochætes of the various relapsing fevers by the following method. A piece of sterile tissue, *e.g.*, kidney of rabbit, is placed in a test-tube; a few drops of citrated blood from an infected animal are added and then 15 c.c. of sterile ascitic or hydrocele fluid. The presence of a loose fibrin is helpful, and growth occurs under ordinary anaerobic conditions. He finds that all the species multiply by longitudinal and probably also by transverse division.

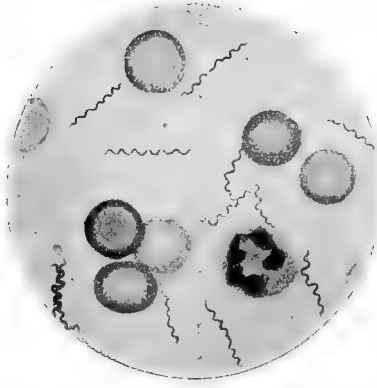

FIG. 152.—Spirochætes of relapsing fever in human blood. Film preparation. (After Koch.) See also Plate IV., Fig. 18. × about 1000.

Relations to the Disease.—In relapsing fever, after a period of incubation there occurs a rapid rise of temperature which lasts for about five to seven days. At the end of this time a crisis occurs, the temperature falling quickly to normal. In the course of about other seven days a sharp rise of temperature again takes place, but on this occasion the fever lasts a shorter time, again suddenly disappearing. A second or even third relapse may occur after a similar interval. The organisms begin to appear in the blood shortly before the onset of the pyrexia, and during the rise of temperature rapidly increase in number. They are very numerous during the fever, a large number being often present in every field of the microscope when the blood is examined at this stage. They begin to disappear shortly before the crisis: after the crisis they are entirely absent from the circulating blood. A similar relation between the presence of the organisms in the blood and the fever is found in the case of the relapses. Münch in 1876 produced the disease in the

human subject by injecting blood containing the spirochætes, and this experiment has been several times repeated with the same result. Additional proof that the organism is the cause of the disease has been afforded by experiments on animals. Carter in 1879 was the first to show that the disease could be readily produced in monkeys, and his experiments were confirmed by Koch. In such experiments the blood taken from patients and containing the spirochætes was injected subcutaneously. In the disease thus produced there is an incubation period which usually

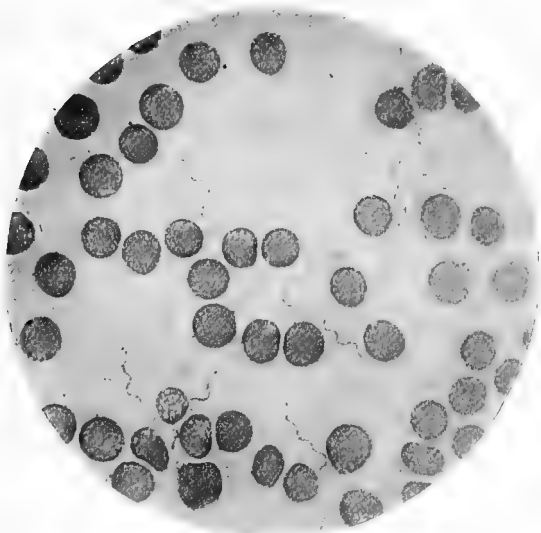

FIG. 153.—Spirochæte obermeieri in blood of infected mouse. × 1000.

lasts about three days. At the end of that time the organisms rapidly appear in the blood, and shortly afterwards the temperature quickly rises. The period of pyrexia usually lasts for two or three days, and is followed by a marked crisis. As a rule there is no relapse, but occasionally one of short duration occurs.[1] White mice and rats are also susceptible to infection. In the former animals the disease is characterised by several relapses; in the latter there is, however, no relapse.

[1] Norris, Pappenheimer, and Flournoy, in their experiments on monkeys with the organism of American relapsing fever, found that several relapses occurred.

Immunity.—Metchnikoff found that during the fever the spirochætes were practically never taken up by the leucocytes in the circulating blood, but that at the time of the crisis, on disappearing from the blood, they accumulated in the spleen and were ingested in large numbers by the microphages or polymorpho-nuclear leucocytes. Within these they rapidly underwent degeneration and disappeared. It is to be noted in this connection that swelling of the spleen is a very marked feature in relapsing fever. These observations were confirmed by Soudakewitch, who also found that when the disease was produced in splenectomised monkeys (*cercocebus fuliginosus*) the spirochætes did not disappear from the blood at the usual time, but rather increased in number, and a fatal result followed on the eighth and ninth days respectively. Later observations, however, indicate that, as in the case of so many other diseases, the all-important factor in the destruction of the organisms is the development of antagonistic substances in the blood. Lamb found in the case of the monkey (*macacus radiatus*) that the removal of the spleen of an animal rendered immune by an attack of the disease did not render it susceptible to fresh inoculation, and he attributed the immunity to the presence of bactericidal bodies in the serum. He found, for example, that *in vitro* the serum of an immune animal brought the movements of the spirochætes to an end, clumped them, and caused their disintegration; and further, that in one case when the spirochætes and the immune serum were injected into a fresh monkey no disease developed. In opposition to Soudakewitch, Lamb found that with a monkey from which the spleen had been removed, death did not occur after it was inoculated with the spirochætes. Observations by Sawtschenko and Milkich, Novy and Knapp, and Rabinowitsch, also show that in the course of infection there are developed anti-substances of the nature of immune-bodies, with protective properties, and agglutinins. Novy and Knapp produced a "hyper-immunity" in rats by repeated injections of blood containing the spirochætes, and found that the serum of such animals had a markedly curative effect, and could cut short the disease in rats, mice, and monkeys. The course of events in the human disease might be explained by supposing that immunity of short duration is produced during the first period of pyrexia, but that it does not last until all the organisms have been destroyed, some still surviving in internal organs or in tissues where they escape the action of the serum or phagocytosis. With the disappearance of the immunity, the organisms appear in the blood, the relapse being, however, of shorter duration and

less severe than the first attack. This is repeated till the immunity lasts long enough to allow all the organisms to be killed. It is possible, however, that the survival of rèsistant spirochætes, or "mutants," may play a part in the production of the relapses.

Varieties.—As already stated, relapsing fever has been studied in different parts of the world, and, apart from the African tick fever, European, Asiatic, and American types have been distinguished. Differences have been made out with regard to clinical features, pathogenic effects, and immunity reactions. It has been shown, for example, by the work of Novy, Strong, and Mackie, that the American spirochæte is probably a distinct species, as animals immunised against it are still susceptible to infection by the European and Asiatic organisms, and *vice versa*. The relationship between the two latter is certainly closer, and no distinct immunity differences have been established. Relapsing fever in Asia is evidently a much more severe disease than in Europe; Mackie gives the mortality in Bombay at the comparatively high figure of 38 per cent. But differences in this respect, as well as in pathogenic effects, may simply depend on variations in virulence. At present no definite statement can be made on this point. Sergent aud Foley have described a type of relapsing fever occurring in Algiers, which they consider to be different from the recognised forms, and have given the name sp. berbera to the organism concerned; and Balfour has observed cases in Khartoum which he thinks are probably of the same nature.

The fact that tick fever and other spirilloses are conveyed by the bites of insects makes it extremely probable that relapsing fever is transmitted in this way. At first the bed-bug was believed to be the vehicle of transmission, and the experiments of Karlinski and of Tictin, which showed that the spirochætes might remain alive and virulent in the body of this insect for some time after it had sucked the blood of a patient, lent some support to this view. Attempts to transmit the disease by means of the bites of bugs were, however, generally unsuccessful; Mackie produced the disease in only one out of six monkeys used for this purpose, though large numbers of bugs, which had bitten relapsing fever patients, were used. On investigating an epidemic of the disease, however, he obtained a considerable amount of evidence on epidemiological grounds that the disease was carried by the body louse. He also found that the spirochætes in the blood which had been ingested underwent great multiplication about three days afterwards, and formed large tangled masses in the stomach contents. The view that the

louse is the agent of transmission of the human disease is strongly supported by the experiments of Manteufel, who was able to transmit infection from rat to rat in nearly 60 per cent. of the experiments made, whereas he obtained only negative results by means of bugs. Fehrmann considers that the clothes louse may carry the infection. Further observations are still necessary.

African Tick Fever.

The disease long known by this name as prevalent in Africa

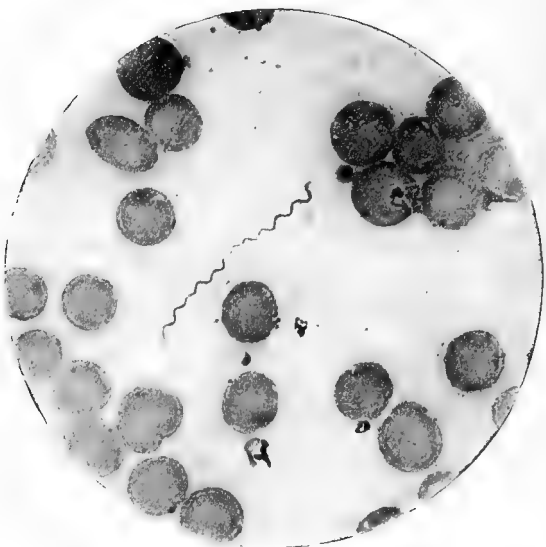

FIG. 154.—Film of human blood containing spirochæte of tick fever. × 1000.[1]

has also been shown to be caused by a spirochæte—*sp. duttoni.* Organisms of this nature had been seen in the blood of patients in Uganda by Greig and Nabarro in 1903, and Milne and Ross in the end of 1904 recorded a series of observations which led them to the conclusion that tick fever was due to a spirochæte. It is, however, chiefly owing to the work of Dutton and Todd in the Congo Free State, on the one hand, and of Koch in

[1] We are indebted to Col. Sir William Leishman, R.A.M.C., for the preparations from which Figs. 153–55 were taken.

German East Africa, on the other, that our knowledge of the etiology of the disease has been obtained.

The following are the chief facts regarding this fever. Clinically, the fever closely resembles relapsing fever, but the periods of fever are somewhat shorter, rarely lasting for more than two or three days. It is seldom attended with a fatal result unless in patients debilitated by other causes. The organisms in the blood are considerably fewer than in the case of European

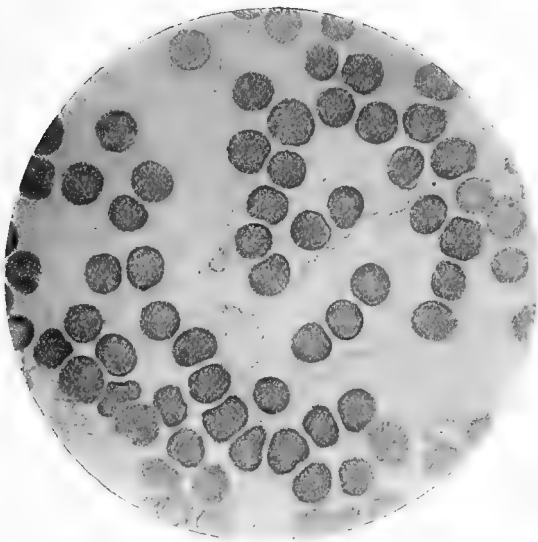

FIG. 155.—Spirillum of human tick fever (spirillum duttoni) in blood of infected mouse. ×1000.

relapsing fever, and sometimes a careful search may be necessary before they are found. Morphologically, they are said to be practically identical, although Koch thought that the organisms in tick fever tended on the whole to be slightly longer; the average length may be said to be 15–35 μ. Dutton and Todd showed that it was possible to transmit the disease to certain monkeys (*cercopitheci*) by means of ticks which had been allowed to bite patients suffering from the disease, the symptoms in these animals appearing about five days after inoculation. The disease thus produced is characterised by several relapses, and

often leads to a fatal result. In one case they produced the disease by means of young ticks hatched from the eggs of ticks which had been allowed to suck the blood of fever patients, and they came to the conclusion that the spirochætes were not simply carried mechanically by the ticks, but probably underwent some cycle of development in the tissues of the latter. Leishman has since shown that the ticks of the second generation may also be infectious. The species of tick concerned is the *ornithodorus moubata*. These results were confirmed and extended by Koch. He found that after the ticks had been allowed to suck the blood containing the organisms, these could be found for a day or two in the stomach of the insect. After this time they gradually disappeared from the stomach, but were detected in large numbers in the ovaries of the female ticks, where they sometimes formed felted masses. He also traced the presence of the spirochætes in the eggs laid by the infected ticks, and in the young embryos hatched from them. On the other hand, Leishman has failed to find any evidence of spirochætes in the tissues of ticks later than ten days after ingestion of blood containing them, or in the ova laid by the ticks, or in the young ticks when hatched, though these were proved by experiment to be infective. After ingestion of the blood by the ticks, he found that morphological changes occurred in the spirochætes, resulting in the formation of minute chromatin granules which traverse the walls of the intestine and are taken up by the cells of the Malpighian tubules; they also penetrate the ovaries and may be found in large numbers within the ova. Similar granules are to be seen in the Malpighian tubules of the embryo ticks, where they are also found in the subsequent stages of their life. He has proved that infection of animals may be produced by inoculation with crushed material containing the granules but no spirochætes. He accordingly considers that the granules in question represent a phase in the life-history of the parasite, and that infection occurs by inoculation of the skin with the chromatin granules voided in the Malpighian secretion and not by unaltered spirochætes from the salivary glands. A similar view is taken by Hindle, who has found that when infected ticks, in which the spirochætes have disappeared, are heated to a temperature of 35° C., the spirochætes reappear in the organs and cœlomic fluid. It is also interesting to note that Balfour has found similar granules in ticks (*argas persicus*) infected with *spirochæte gallinarum*, and he has also observed the formation of granules from spirochætes in the blood of Sudanese fowls treated with salvarsan.

Koch also made extensive observations on the ticks in German East Africa, and found that of over six hundred examined along the main caravan routes 11 per cent. contained spirochætes, and in some localities almost half of the ticks were infected. In places removed from the main lines of commerce he still found them, though in smaller number. It has also been demonstrated that in some places the ticks are found to be infected with the spirochætes although the inhabitants do not suffer from tick fever, a circumstance which is probably due to their having acquired immunity against the disease.

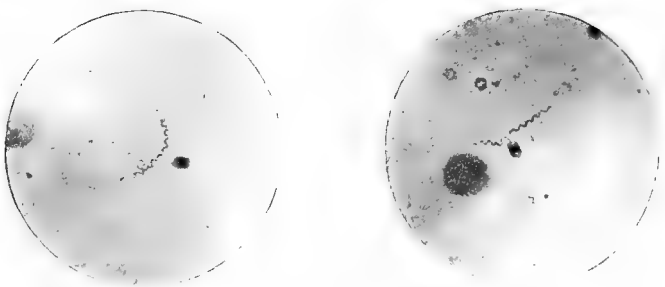
It is now generally believed that the sp. duttoni is a species distinct from, though closely allied to, the organisms of the relapsing fevers described above. We have mentioned some differences in the clinical characters of the diseases, and there are also differences in the pathogenic effects of the organisms on inoculation. The sp. duttoni, for example, produces a much more severe disease in monkeys, and is pathogenic to more species of the laboratory animals than the sp. obermeieri. The most important differences are, however, brought out by immunity reactions. It was shown by Breinl that the immunity produced by the sp. obermeieri did not protect against the sp. duttoni, and that the converse also held good; and it has since been established that a similar difference obtains between the sp. duttoni and the organisms of the Asiatic and American varieties of relapsing fever. Corresponding results are obtained on testing the various serum reactions *in vitro*. As already stated, Noguchi has cultivated the sp. duttoni outside the body, and from a study of its characters agrees that it is a distinct species.

Syphilis.

The cause of syphilis is the organism discovered by Schaudinn and Hoffmann in 1905 and called by them the *spirochæte pallida*, now often known as the *treponema pallidum*. They described its characters and its occurrence in syphilitic lesions, and their observations have been fully confirmed. Its recognition, at first somewhat difficult, has been rendered comparatively easy by the introduction of new methods.

Spirochæte pallida.—This is a minute spiral-shaped organism, showing usually from eight to twelve curves, though longer forms are met with; the curves are small (each measuring a little over 1 μ), comparatively sharp, and regular (Figs. 156, 157, 158). It may be said to measure 4 to 14 μ in length, while it is extremely

thin, its thickness being only ·25 μ. In a fresh specimen, say, a scraping from a chancre suspended in a little salt solution, the organism shows active movements, which are of three kinds—rotation about the long axis, gliding movements to and fro, and movements of flexion of the whole body; there is little actual locomotion, and a specimen will often remain in the same field for a long time. The ends are pointed and tapering, and, as was first shown by Schaudinn, a flagellum is present at each end. Both in fresh specimens and in dried films (Figs. 156–158) the regularity of the spirals is well maintained, though in the latter there is sometimes distortion or drawing out of a spiral. The use of dark-ground illumination (p. 90) is of great service in searching for the organism.



FIGS. 156 and 157.—Film preparations from juice of hard chancre showing spirochæte pallida. Giemsa's stain. ×1000. (From preparations by Dr. A. MacLennan.)

In ulcerated syphilitic lesions, and also in non-syphilitic lesions of the genitals, other organisms are, of course, present, and not infrequently various other spirochætes. Of these several species have been described, e.g., *sp. refringens*, *sp. balanitidis*, *sp. gracilis*, but there are others which have not yet been differentiated. The first mentioned is a comparatively coarse organism, more highly refractile, while its curves vary during the movements; in film preparations the curves appear irregular or are lost to a large extent. Some of the other species are of smaller size, but they differ from the sp. pallida in their appearance and in the character of their movements. We believe that in the case of genital lesions there is little difficulty to the experienced observer in recognising the sp. pallida, but any difficulty will be removed if the superficial organisms are removed and the lymph is taken from the lesion for examination.

These organisms generally stain deeply with Giemsa's stain and are of a bluish tint; the sp. pallida is coloured a faint pink. In lesions of the mouth and probably in some others, *e.g.*, fœtid ulcerations, etc., there occur, however, spirochætes which are indistinguishable morphologically from the sp. pallida, *e.g.*, the sp. microdentia and sp. mucosa, found in carious teeth and pyorrhœa alveolaris. Both of these organisms have been cultivated by Noguchi; they have been proved to be devoid of pathogenic properties, and the cultures, moreover, have a foul odour. The sp. pertenuis of yaws (p. 524) has also the same

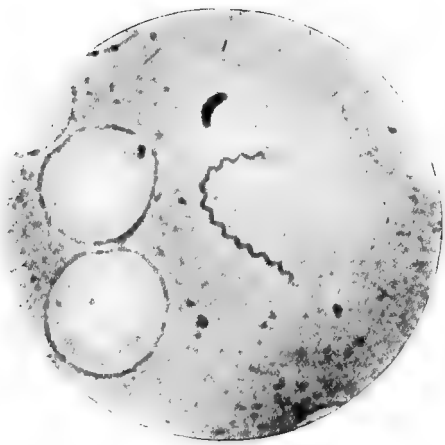


FIG. 158. -Film preparation from juice of hard chancre showing spirochæte pallida. Giemsa's stain. ×2000. (From a preparation by Dr. Haswell Wilson.)

microscopical appearances. In the microscopical diagnosis of the organism of syphilis, just as in the case of the tubercle bacillus (p. 286), an all-important point is, accordingly, the source of the organism; and we may say that if we except the case of yaws, which does not occur in this country, an organism with the characters described above can be identified with certainty as the sp. pallida provided that it is obtained from the *substance* of the tissue lesion. The spirochæte pallida by the Giemsa stain is coloured somewhat faintly, and of reddish tint, whilst the regular spiral twistings are preserved; the sp. refringens shows flatter, wave-like bends (Fig. 160), and, like other organisms, is stained of a bluish tint.

Noguchi, on studying different strains of the sp. pallida in cultures, found that they varied in thickness, and he was able to distinguish thick, thin, and intermediate types. He also found that they differed in their pathogenic action, the thick forms on injection into the testicle of a rabbit causing nodular lesions of cartilaginous hardness, the thin forms producing a diffuse indurative lesion. These observations are suggestive as possibly throwing some light on the variations in the effects in the human subject.

The number of publications with regard to the distribution of

FIG. 159.—Section of spleen from a case of congenital syphilis, showing several examples of spirochæte pallida. Levaditi's method. ×2000.

the spirochæte pallida is now very large, and a summary of the results may be given. In the primary sore and in the related lymphatic glands, the juice of which can be conveniently obtained by means of a hypodermic syringe, the organism has been found in a very large majority of cases. It has been also obtained in the papular and roseolar eruptions, in condylomata and mucous patches—in fact, one may say generally, in all the primary and secondary lesions. Schaudinn in his last series of cases, numbering over seventy, found it in all, and on a few occasions detected it in the blood during life in secondary syphilis. It has also been obtained from the spleen during life. In the congenital form of the disease the organism may be present in

large numbers (Plate II., Fig. 6), as was first shown by Buschke and Fischer, and by Levaditi. In the pemphigoid bullæ, in the blood, in the internal organs, the liver, lungs, spleen, suprarenals, and even in the heart its detection may be comparatively easy, owing to the large numbers present (Fig. 159). It is also present in syphilitic placentæ, though not usually in large numbers. It has been generally supposed that tertiary syphilitic lesions are non-infective, and the results of the earlier observations on the spirochæte pallida were apparently in accordance with this view, as they gave negative results. More prolonged search has, however, shown that the organism may occur in tertiary lesions also. It has been found to be present in the peripheral parts of gummata, especially at an early stage of their formation; and the observations of Schmorl, Benda, J. H. Wright, and others show that it is often to be found in syphilitic disease of arteries, sometimes occurring in considerable numbers in the thickened patches in the aorta. That the spirochæte may persist in the body for a very long time after infection, has been abundantly shown by different observers; in one case, for example, its presence was demonstrated sixteen years after the primary lesion. It can readily be demonstrated in sections of syphilitic lesions by the method described on page 109. Recently Noguchi and Moore have announced the discovery of the spirochæte in the brain in general paralysis of the insane in a certain proportion of cases. The organism was seen in all the layers of the cerebral cortex, with the exception of the outermost, and the cases in which it was found had run a relatively rapid course. Infection has also been transmitted to the rabbit (*vide infra*) by inoculation with the brain tissue of general paralytics.

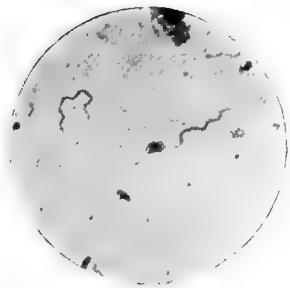

FIG. 160.—Spirochæte refringens in film preparation from a case of balanitis. ×1000.

In preparations from the organs in congenital syphilis large numbers of spirochætes, chiefly extra-vascular in position, can be seen, and many may occur in the interior of the more highly specialised cells, for example, liver-cells. They also abound sometimes on mucous surfaces, *e.g.*, of the bladder and intestine in cases of congenital syphilis. The enormous numbers of the

organism which may be present in a well-preserved condition in macerated fœtuses render it probable that the organism may multiply in the dead tissues under anaerobic conditions.

Cultivation.—Although Mühlens and Hoffmann had previously obtained pure cultures of an organism morphologically identical with the spirochæte pallida, it is chiefly to Noguchi that we owe the methods of cultivation. We shall accordingly state his results, which in certain respects differ from those of the other two observers. In the first instance his cultures were made from syphilitic lesions in the rabbit, but later directly from the lesions of the human disease. As a culture medium he used a mixture of two parts of 2 per cent. agar and one part of ascitic or hydrocele fluid, to which a small portion of sterile rabbit's kidney or other organ was added, the medium being placed in deep tubes and covered with a thick layer of paraffin oil. The medium was inoculated through the oil, the maintenance of strict anaerobiosis being essential. When contaminating bacteria were present these formed a thick growth along the line of inoculation, whilst the spirochætes grew as a diffuse haze into the surrounding medium. By making sub-cultures from parts apparently free from bacterial growth he succeeded in obtaining the organism in the pure condition. At first the organisms were small, but after several days they had the usual length of the spirochæte pallida and all its characteristics. An important point is that he found clear evidence that the organism multiplies by longitudinal division. On inoculating monkeys (*macacus* and *cercopithecus*) by scarification, in some cases indurated syphilitic papules developed and the blood of the animals gave a positive Wassermann reaction. The etiological relation of the organism has thus been completely established.

Transmission of the Disease to Animals.—Although various experiments had previously been made from time to time by different observers, in some cases with reported successful result, it is to the papers of Metchnikoff and Roux (1903–5) that we owe most of our knowledge. These observers carried on a large series of observations, and showed that the disease can be transmitted to various species of monkey. Of those the anthropoid apes are most susceptible, the chimpanzee being the most suitable for experimental purposes. Their results have been confirmed by Lassar, Neisser, Kraus, and others. The number of experiments on these animals is now very great, and the general result is that the disease has been transmitted by material from all the kinds of syphilitic lesions in which spirochætes have been demonstrated, including tertiary lesions and

even the blood in secondary syphilis. Inoculation is usually made by scarification on the eyebrows or genitals; the subcutaneous and other methods of inoculation, with the exception of intratesticular, give negative results. The primary lesion is in the form of an indurated papule or of papules, in every respect resembling the human lesion. Along with this there are marked enlargement and induration of the corresponding lymphatic glands. The primary lesion appears on an average about thirty days after inoculation, and secondary symptoms develop in rather more than half of the cases after a further period of rather longer duration. These are of the nature of squamous papules on the skin, mucous patches in the mouth, and sometimes palmar psoriasis. As a rule, the secondary manifestations are of a somewhat mild degree, and in no instance has any tertiary lesion been observed, though this may be due to the animals not having lived long enough. By re-inoculation from the lesions, the disease may be transferred to other animals. The disease may also be produced in baboons and macaques, but these animals are less susceptible, and secondary manifestations do not appear. The severity of the affection amongst apes would in fact appear to be in proportion to the nearness of the relationship of the animal to the human subject. The blood of the infected animals comes to give a positive Wassermann reaction.

As shown first by Hänsell, and afterwards by Bertarelli, the eye of the rabbit is susceptible to inoculation from syphilitic lesions. The material used is introduced in a finely divided state either into the tissue of the cornea or into the anterior chamber, and syphilitic keratitis or iritis, or both, may result, there being a period of incubation of at least two weeks. Levaditi and Yamanouchi have studied the stages in detail, and find that the spirochætes remain in the inoculated material unchanged for a time; then organisation occurs and the spirochætes multiply, and later still there is a more rapid multiplication and invasion by them of the tissues of the eye. The period of incubation is thus not due to the organism passing through some cycle of development, but simply to its requiring certain conditions for multiplying which are not supplied for some time. The testis of this animal is also a convenient site of inoculation, a syphilitic orchitis being set up, and the disease has been maintained by this method through several generations of animals. The intratesticular method has proved of great value in testing the infectivity of suspected material, and by this means it has been shown that spirochætes from gummata are

not attenuated in virulence. Uhlenhuth and Mulzer produced generalised syphilitic lesions in young rabbits by intracardiac inoculation with syphilitic material. They have also found that the organism can pass through the placenta of the rabbit and infect the fœtus.

It has long been held that a person suffering from syphilitic disease is not susceptible to a fresh infection, and this has been shown by experimental methods to hold in the artificially produced disease in the ape, the possibility of re-inoculation thus indicating freedom from infection. A considerable number of cases in the human subject have been observed where after treatment with salvarsan a second attack of the disease has been contracted, the inference being that the first attack had been completely cured. In the case of the rabbit, however, it has been found possible to produce a fresh syphilitic lesion when another was still in existence on the cornea. Apparently in this animal the effects of this local lesion do not become general in the same way as in man.

The experimental production of the disease has supplied us with some further facts regarding the nature of the virus. It has been shown repeatedly that the passage of fluid containing the virus through a Berkefeld filter deprives it completely of its infectivity; in other words, it does not belong to the ultra-microscopic group of organisms. The virus is also readily destroyed by heat, a temperature of 51° C. being fatal. With regard to the production of immunity, very little of a satisfactory nature has so far been established. It has been found that the virus from a macaque monkey produces a less severe disease in the chimpanzee than the virus from the human subject, inasmuch as secondary lesions do not follow; the virus would thus appear to have undergone a certain amount of attenuation in the tissues of that monkey. The presence of the spirochæte does not lead to the formation of anti-substances to any marked extent. There is some evidence that the serum from a patient suffering from the disease when mixed with the virus before inoculation modifies the disease to a certain extent, but further evidence on this point is necessary.

Luetin.—Noguchi has prepared an extract from pure cultures of the spirochæte pallida, which he calls *luetin*, and he finds that this gives a characteristic cutaneous reaction in syphilitics. This reaction is analogous to the tuberculin reaction in tuberculosis, and, like it, appears to depend on a condition of super-sensitiveness or allergy (p. 595). In a normal individual the intradermic inoculation of luetin produces a local erythema which may

sometimes go on to the formation of a slight papule on the second day; thereafter the reaction recedes. In the case of syphilitics Noguchi distinguishes three types of positive reaction—(*a*) *papular form*, in which a large indurated, reddish papule, 5–10 mm. in diameter, forms and increases for three or four days, the colour becoming dark bluish red; (*b*) *pustular form*, in which the inflammatory change is more severe, the papule changing into a vesicle and then into a pustule; and (*c*) *torpid form*, in which, after a latent period of about ten days, reaction appears and goes on to the formation of a small pustule. Noguchi's claims as to the clinical value of the reaction are supported by other observers. The results obtained so far show that a positive result is got when the disease is latent and often when the Wassermann reaction is negative. It is often absent in secondary syphilis, but may appear after anti-syphilitic treatment has been carried on for some time. Further elucidation of the nature of the reaction is still required.

Serum Diagnosis—Wassermann Reaction.—The method of applying this test has already been given (p. 127); we have now to consider the results of its application. On comparing the results obtained it will not be an overestimate to say that a positive result may be obtained in at least 90 per cent. of cases where there is evidence of active general infection. The reaction generally appears first on the fifteenth to thirtieth day after appearance of the sore, and then gradually becomes more marked; during the period of secondary manifestations it is practically always present; in the tertiary stage with active manifestations a positive result is only a little less frequent. As the disease becomes inactive or is cured the reaction may disappear, but it is to be noted that disappearance of the reaction after being present does not necessarily imply cure of the disease. It may only have become latent, and on its becoming once more active the reaction may reappear; in fact, its presence would appear to be definitely related to the activity of the syphilitic lesions. A positive reaction is practically always present in general paralysis and in the large majority of cases of tabes, and may be given by the cerebro-spinal fluid as well as by the blood serum in these diseases. As regards other diseases, a positive reaction has been recorded as occurring in leprosy (p. 308) and sleeping-sickness and also in yaws, and occasionally in malaria; but apart from these diseases it is practically never met with. At present little can be said in explanation of the Wassermann reaction. It seems to depend on the interaction of lipoidal substances in the extract with proteins in the serum, which

are apparently contained in the globulin fraction; but we know nothing as to why this peculiar modification of the serum should be present in syphilis. It is now generally accepted that it does not depend on the presence of an anti-substance (immune-body), which in association with the antigen (the spirochæte) fixes complement.

Methods of Examination.—As already said, in the examination of an ulcerated chancre or other lesion it is advisable to get rid of the surface organisms. The surface should be cleaned with saline and dried. A piece of cotton-wool soaked in absolute alcohol or spirit is then applied for about a minute; the alcohol is then washed off with saline, and the surface is again dried. After a short time there is usually a free flow of watery lymph, which is practically free from other organisms, and often contains the spirochaete in large numbers; a small drop of this is placed on a slide, a cover-glass is applied, and the specimen is examined by dark-ground illumination. It is advisable to put a thin ring of vaseline on the slide to support the cover-glass. Dried films also may be made and treated by any of the methods above described (p. 110), of which Fontana's is to be recommended. Others prefer to scarify the margin of the sore and examine the lymph which exudes, the flow of which may be aided by squeezing, or a small incision may be made with a very sharp knife, and then after bleeding has completely stopped to take the small drop of serum which gathers at the site. In all cases admixture of blood is to be avoided, as it interferes with the examination by the dark-ground method. In the case of a lymphatic gland or non-ulcerated lesion it is best to puncture with a hypodermic needle, the point of which should be moved about in the tissue. After it is withdrawn a little saline may be placed in the syringe and pressed through the needle, the first small drop which passes, and which washes out the contents, being taken for examination; here also dark-ground illumination gives the best results.

For methods of cultivation, *vide* p. 520.

Frambœsia or Yaws.

Frambœsia is a disease of the tropics, occurring in the west coast of Africa, Ceylon, the West Indies, and other parts. It is characterised by a peculiar cutaneous eruption, and it is markedly contagious. Its resemblance in many respects to syphilis has been noted, and the relation of the two diseases has been the subject of much controversy. It is accordingly a matter of great interest that an organism of closely similar characters to the spirochæte pallida has been found in the lesions of frambœsia. This organism was discovered by Castellani, who gave to it the name *spirochæte pertenuis* or *pallidula*. Morphologically, it is practically identical with the spirochæte pallida; when ulceration has occurred other spirochætes of less regular form may be present as contaminations. In the skin lesions it has been shown by Levaditi's method to be present in con-

siderable numbers, especially in the epidermis and also amongst the leucocytic infiltration, which comprises more polymorphonuclear leucocytes than are seen in the case of syphilis. Castellani showed that the disease could be transferred to monkeys (*semnopithecus* and *macacus* being used for this purpose), and that the organism could be demonstrated in the unbroken skin lesions. The lesions are as a rule confined to the site of inoculation, but the infection is general, as is shown by the presence of spirochætes in the lymphatic glands and the spleen. These results with regard to the presence of spirochæte pertenuis in the lesions and the inoculation of apes have been confirmed by other workers, and the etiological relationship of the organism to the disease may now be regarded as established. Nichols has shown that a frambœsia lesion can be produced in the testicle of the rabbit of similar character to the syphilitic lesion, though the period of incubation is shorter. He finds that the best means of distinguishing the two diseases is afforded by inoculating the skin of the monkey. In the case of syphilis the resulting lesion is flat, dry, and very scaly; in the case of frambœsia it is elevated, slightly scaly, and very œdematous; here also the period of incubation is shorter in the case of frambœsia. The immunity reactions in monkeys infected with syphilis and frambœsia, as experimentally studied by Castellani and by Neisser, Baermann, and Halberstädter, go to show that the two diseases are distinct. Nichols obtained a corresponding result in the case of the rabbit, as he found that this animal, when cured of a syphilitic lesion of the testicle by means of salvarsan, was susceptible to frambœsia but not to syphilis. On the other hand, Levaditi and Nattan-Larrier found that, although monkeys infected with syphilis were refractory to frambœsia (*Fr. pian*), monkeys infected with frambœsia were susceptible to syphilis: they therefore concluded that frambœsia is a modified or mild form of syphilis. We may add that patients suffering from frambœsia generally give a positive Wassermann reaction; they are also very amenable to treatment with salvarsan (Alston and others). The exact relationship of the two diseases cannot be yet accurately defined, but they are probably distinct, though undoubtedly closely related.

Spirochætal or Infective Jaundice.

This affection, often known as Weil's disease, was proved in 1915 by Inada and other Japanese workers to be due to a spirochæte, to which they gave the name *spirochæte icterohæmorrhagiæ*, and already the pathology of the condition

has been worked out fairly fully. The disease is characterised by irregular pyrexia, often severe jaundice, which usually appears about the fourth day of illness and may become very marked, a tendency to hæmorrhage from mucous surfaces and into the tissues, hæmorrhagic herpes, etc., albuminuria, and various other symptoms. Its occurrence in small epidemics had been previously noted, members of the same family or groups of soldiers in barracks being not infrequently affected; in Japan it was found to occur amongst workers in the same part of a mine. It has occurred during the war amongst the troops in France, and the results of the

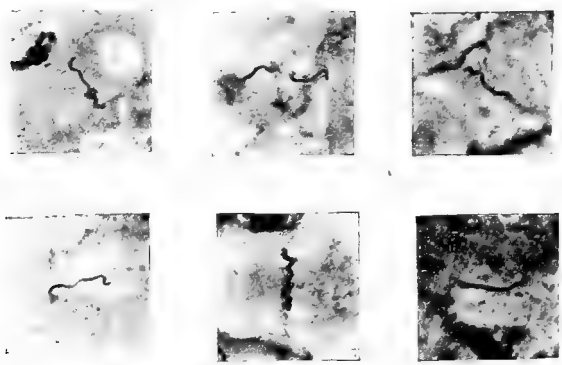

FIG. 161.—Specimens of spirochæte ictero-hæmorrhagiæ, as seen in sections of a suprarenal of an infected guinea-pig. Stained by Levaditi's method.
(From a preparation by Major J. W. M'Nee, R.A.M.C.) ×1000.

Japanese workers have been confirmed by bacteriologists in both the British and French armies. It has also been found on the Italian front and amongst the German troops. The infection has thus had a wide distribution during the war, but the mortality has been much lower than that met with in Japan.

Morphology of the Spirochæte.—The organism in the blood and tissues measures 6–9 μ in length, but both shorter and longer forms occur, and about ·25 μ in thickness; that is, it is a slender organism of about the thickness of the sp. pallida. In cultures it may grow into much longer threads. It is somewhat thicker in the middle and tapers towards the ends, which may be pointed, but there are no terminal flagella; its substance may appear somewhat granular. It presents usually several

spirals, but these are somewhat irregular and often poorly marked (Fig. 161); not infrequently the ends form small hooks. It is motile, the movements being rotatory, undulatory, and also to and fro. It can be studied by all the microscopic methods already described in the case of the sp. pallida (p. 524).

Cultivation.—The organism was first successfully cultivated in Noguchi's medium for sp. pallida, in which the initial growth survives for three to six weeks. The medium remains clear and does not yield any odour. Later it was grown on solid media, blood agar and blood gelatine, the latter being the more suitable. The limits of growth are wide, namely, 15–37° C., the optimum temperature being 22–25° C. Noguchi recommends the following media as suitable; he finds that the addition of sterile tissue does not improve the growth :—

(*a*) Rabbit serum, two parts; Ringer's solution or 0·9 per cent. sodium chloride solution, six parts; citrated rabbit plasma, one part.

(*b*) The same with the addition of one to two parts of neutral or slightly alkaline agar (2 per cent.), which should be liquefied and added when quite hot (60–65° C.) in order to get a uniform mixture of the agar.

Both media are covered with a layer of sterile liquid paraffin, and inoculation is made through the paraffin. In these media growth produces slight turbidity.

Relations to the Disease.—The organism occurs both in the blood and in the organs. In the former it is found in the first four or five days of the disease; thereafter it gradually disappears, and in the second week, when jaundice is most marked, it cannot be detected. The best method of demonstrating its presence is to draw off some blood, say, 3 c.c., and inject it into the peritoneal cavity of the guinea-pig, in which animal it produces an infection and can easily be found (*vide infra*). It is rarely present in the blood in the human subject in numbers sufficient to allow its detection by microscopic examination.

Of the internal organs the liver contains the organisms in largest quantities; they may be also found in the suprarenals, and, especially at a later stage, in the kidneys. In all the organs in the human subject the spirochætes are scanty, they are often somewhat irregular and degenerated in appearance, and often in the interior of the special cells. These facts have been explained as being the result of the formation of anti-substances, which drive them from the blood and interstitial tissues. Their late occurrence and persistence for some time in the kidneys are comparable with what occurs in the natural infection of the rat without the occurrence of disease symptoms (*vide infra*). The spirochæte is also excreted in the urine.

This does not occur in the earliest stage of the disease, but from about the tenth day onwards positive results are obtained in increasing numbers, till about the twentieth day it may be found in practically all cases. Thereafter it gradually disappears, and is rarely found after the fortieth day. The best method is to examine by dark-ground illumination the deposit thrown down from the urine by a high-speed centrifuge.

The gradual development of anti-substances in the blood has been shown to occur during the disease. These appear towards the end of the first week, and seem to be related to the disappearance of the organism from the blood; they become specially marked during the second week. Their presence can be demonstrated by injecting some of the patient's serum along with the spirochætes into a guinea-pig, death being thus prevented, or at least the onset of the illness being postponed. Destruction of the organisms under the influence of the anti-serum may be observed in the peritoneal cavity of the animal, that is, spirochætolysis occurs, corresponding to Pfeiffer's phenomenon in the case of bacteria.

Experimental Inoculation.—The injection of blood or of emulsions of organs containing the spirochætes into the peritoneal cavity of a guinea-pig leads to an infection which is usually fatal in about seven to twelve days; the same holds with regard to the effect of pure cultures. The symptoms are conjunctival congestion, anæmia, jaundice, hæmorrhagic diathesis, and albuminuria. There is pyrexia, which towards the end is succeeded by subnormal temperature; the jaundice occurs somewhat late, usually about twenty-four hours before death. *Post mortem*, there are hæmorrhages in the lungs, intestinal walls, and retro-peritoneal tissue; acute parenchymatous nephritis is present, and the spleen is large and congested. The hæmorrhages in the lungs occur as small and large spots, described as being "like the wing of a mottled butterfly." The spirochætes are present in the blood and organs, and in the latter are chiefly interstitial in position, few being actually within cells. In this respect there is a difference from what obtains in the human disease. They are most abundant in the liver, where they may be arranged like a garland round the liver cells. The adrenals and the kidneys contain considerable numbers, but they are scanty in the spleen, bone-marrow, and lymphatic glands. The Japanese workers believe that, in the human disease, infection occurs chiefly through the alimentary tract, and they were able to produce the disease in the guinea-pig by feeding with material containing the organism or by introducing some of it into the

rectum. They also showed that infection could take place through the apparently intact skin, and found that this occurred with comparative rapidity, as the application of an antiseptic five minutes after the infective material did not prevent infection.

A highly important point with regard to the epidemiology of the disease is the common presence of the spirochæte in both house and field rats without any apparent disturbance of health. This has been established now with regard to rats in Japan, in the trenches at the front, and also in America; and it has been found that the proportion of infected rats is a high one, sometimes over 30 per cent. In these animals the organisms are practically confined to the kidneys, and we have here a resemblance to what is found in the human infection, at a later stage when immune-substances are present in the blood. The spirochætes are passed in large number in the urine of the infected animals, and in this way contamination of the soil and various articles is brought about. The spirochætes obtained from rats are found to vary considerably in virulence.

Rat-bite Fever.

More than one form of infection may be produced by the bite of rats. In the form which is commonest in Japan, Futaki and his associates in 1915 found a spirochæte in the skin lesion and in the lymph-glands. Their results have been confirmed by other Japanese workers, and the organism, now called the *spirochæte morsus muriurn*, has been established as the cause of the infection. The clinical symptoms are inflammation of the bitten parts, paroxysms of fever of the relapsing type, swelling of the lymph glands, and eruption of the skin, all occurring after an incubation period usually of ten to twenty-two days, or longer. The spirochæte, which also occurs in the blood as well as locally, is somewhat short, measuring 2–5 μ, and has a few steep and fairly regular curves of 1 μ each; it is, however, distinctly thicker than the sp. pallida. It has a distinct and fairly long flagellum at each end, and it is actively motile, the movements being very rapid, like those of a vibrio, and distinguishing it from other pathogenic spirochætes. It has been cultivated outside the body and has been proved to be virulent to mice, rats, and other animals. It has been found in rats in the natural condition, in 3 per cent. of house rats, and the disease has been produced in the guinea-pig by allowing a rat infected with the spirochæte to bite it. The infection has been shown to be very amenable to treatment by salvarsan, and the blood of a convalescent patient has been found to possess protective properties.

It is of interest to note, however, that Schottmüller obtained a streptothrix by culture from the blood in a case of rat-bite fever, and Blake has found the same organism both in the blood and in the cardiac vegetations in another case. Further, Douglas, Colebrook, and Fleming have recently published a case in which the infection was due to a streptococcus. It is thus clear that definition in the nomenclature is required.

CHAPTER XXI.

PATHOGENIC FUNGI.

In pathological bacteriology, besides the bacteria themselves, higher organisms belonging to the group of fungi not infrequently claim attention. On the one hand, cultures may be contaminated with the spores of the omnipresent terrestrial forms growing in all decaying material, and on the other hand, fungi of the same type are known to be the causal agents in certain diseases. Before considering the latter, with which we are more intimately concerned, we shall first give a short account of the group of fungi as a whole and of some of the common saprophytic forms. For this we are indebted to the kindness of Professor Percy Groom.

The overwhelming majority of fungi consist of tubular branched filaments, termed *hyphæ*, each of which has a thin continuous wall within which are the protoplasmic and other contents. The whole body of the fungus thus composed of hyphæ is termed the *mycelium*. This may be loose and web-like in texture, as in the case of common moulds, or may assume the form of a compact skin or mass which is produced by the copious branching and close interweaving of the hyphæ, as in ordinary toadstools.

In the *Phycomycetes*, a lowly organised group of fungi, the hyphæ are typically continuous tubes devoid of any cross septa, excepting where reproductive organs or cells occur; whereas in the more highly organised fungi, *Mycomycetes*, the hyphæ are segmented by transverse walls.

Inasmuch as fungi have descended from algæ, which are mainly aquatic, those fungi that are most alga-like betray in their life-history signs of the aquatic mode of existence. Thus in a number of Phycomycetes the ends of certain hyphæ become shut off by a transverse wall. The terminal chamber becomes swollen and its abundant protoplasm divides into a number of cells, which, by rupture of the outer wall, escape as naked ciliated *swarm-spores*. Each of these swims about in water (raindrops and so forth), eventually clothes itself with a thin cell-wall, and, emitting a hypha which grows and branches, develops into a new plant. The terminal organ within which these *asexual spores* arise is termed a *sporangium*. In other types of Phycomycetes, for instance *Mucor mucedo* (Fig. 162), the spores arising in the same manner inside a sporangium acquire a cell-wall before rupture of the sporangium wall:

in this case the walled spores are not swarm-spores, but are adapted for dispersal through the air.

Some of the Phycomycetes can produce spores asexually in an entirely different manner, namely, externally by abstriction from the end of a hypha. Such asexual spores externally cut off are termed *conidia*, and the special hypha bearing the conidia, if different in form from the vegetative hyphæ, is termed a *conidiophore*. Each conidium can emit one or more hyphæ and thus give rise to a new plant.

Other forms of asexual spores occurring in these simple fungi include *oidia*, in which a hypha undergoes cross septation into a number of short segments, each of which acts as an asexual spore. A hypha in this oidial condition has a resemblance to a greatly magnified row of bacteria; indeed according to one theory bacteria represent merely oidial conditions of very degenerate fungi.

Finally, as opposed to the thin-walled asexual spores so far mentioned, thick-walled asexual spores (often termed *chlamydospores*) occur in some of these simple fungi, and are endowed with greater powers of resistance to hostile external conditions and act as resting-spores.

Phycomycetes also reproduce sexually. In the simplest case, as represented by *Mucor mucedo*, the ends of two hyphæ come into contact and the terminal parts of the hyphæ are segmented off by a transverse wall. The wall at the region of contact of the two hyphæ is dissolved, and the protoplasmic contents of the two terminal compartments fuse and produce around the resultant mass a thick wall. This thick-walled structure is capable of growing out to produce a new plant. As it is produced by the fusion of two similar sexual cells it is termed a *zygospore*. Those Phycomycetes that have no marked structural distinction between male and female cells or organs, and whose sexually produced cells are therefore zygospores, are grouped together to form the class *Zygomycetes*.

In other Phycomycetes there is a very clear distinction between, on the one hand, the large female organ, which encloses one or more female cells, the ova or *oospheres*, and, on the other hand, the usually smaller but differently shaped male organ, which contains the equivalent of a number of male cells. The union of some of the protoplasm of the male organ with an oosphere results in the production of a fertilised egg-cell or *oospore*. Those Phycomycetes having this mode of sexual reproduction are grouped together to form the class *Oomycetes*.

Sexually produced cells, zygospore and oospore, germinate vegetatively to produce a new mycelium or in a fructificative manner to produce a sporangium. Now the number of spores inside a sporangium of a Phycomycete is not only great but is at least often variable in the same species. Thus if a plant of *Mucor mucedo* is starved, the number of spores produced in each sporangium is greatly reduced. Similarly in the Phycomycetes the number of conidia produced on a conidiophore is considerable and variable. Sporangia and conidiophores, then, are indefinite in type in these simple fungi.

The more highly organised fungi, the Mycomycetes, differ from the Phycomycetes in that (1) their sporangia or conidiophores are *definite*; (2) the hyphæ are septate, with numerous cross partitions; (3) the sexual process, organs, and cells are so modified as to be more or less difficult of recognition, or even perhaps unrecognisable as such. In any case, the Mycomycetes never have a sexually produced zygospore or oospore capable of developing into an independent vegetating fungus.

Two main series are recognisable in the Mycomycetes. In one series

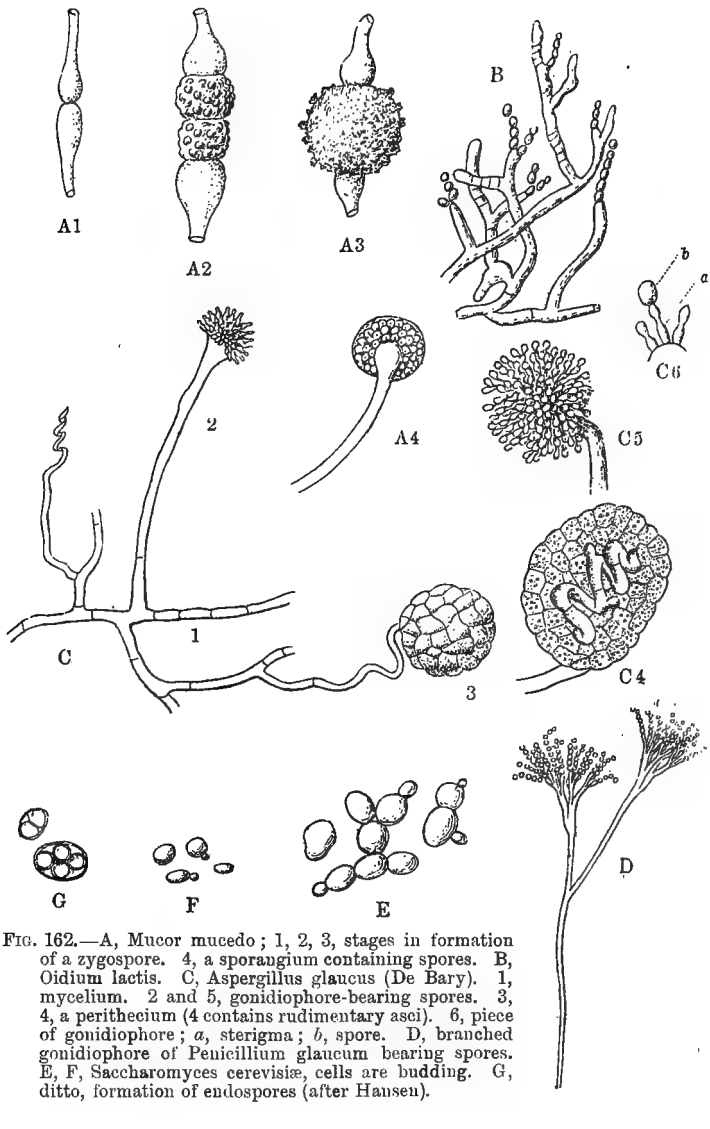

FIG. 162.—A, Mucor mucedo; 1, 2, 3, stages in formation of a zygospore. 4, a sporangium containing spores. B, Oidium lactis. C, Aspergillus glaucus (De Bary). 1, mycelium. 2 and 5, gonidiophore-bearing spores. 3, 4, a perithecium (4 contains rudimentary asci). 6, piece of gonidiophore; *a*, sterigma; *b*, spore. D, branched gonidiophore of Penicillium glaucum bearing spores. E, F, Saccharomyces cerevisiæ, cells are budding. G, ditto, formation of endospores (after Hansen).

the sporangium has become definite in type, as it produces inside it a number of spores that is definite and constant to the species. The number of spores is usually eight, but a few species produce other multiples of two. This definite sporangium is termed an *ascus*, the spores are *ascospores*, and the group of fungi having asci is the *Ascomycetes*. In some of the Ascomycetes the asci are grouped together and form a kind of fructification (ascocarp), which, to give an example, is a closed spherical body in *Aspergillus* and *Penicillium* (*vide infra*).

In the other series of Mycomycetes it is the conidiophore that has become definite in type, being constant and defined in form and numbers of conidia produced. The conidiophore usually bears four conidia or, in a few species, two or a multiple of two. Such a conidiophore is termed a *basidium*, and characterises the class *Basidiomycetes*, of which the common toadstools are examples.

There are some groups of fungi whose characters are sufficiently well known and defined as to be capable of diagnosis, and yet do not accord in characters with any of the classes already mentioned. One of these groups —that of the true rust-fungi, *Ustilaginaceæ*—belongs to the Mycomycetes: among the salient features belonging to the members is their capacity to produce thick-walled asexual resting-spores, which in germination give rise to a minute plant that buds off indefinite numbers of conidia. The other group, the *Chytridiales*, on the contrary is a collection of minute fungal parasites so exceedingly low in organisation as to have feebly denoted or no filamentous hyphæ.

The life-histories of some fungi placed in the groups already enumerated are incompletely known, yet certain characteristic stages are known, so that it is possible to refer these types to their correct systematic position and class. But there still remain many kinds of fungi that are known only in their conidial stage, and the conidiophores are indefinite in type (not basidia). These imperfectly known fungi cannot be placed in their natural classes and have to be empirically grouped according to the arrangement and form of their conidiophores, structure and colour of their conidia, and so forth. They form the large unnatural group *Fungi Imperfecti*. Finally, there remain a few parasitic fungi known only in a sterile mycelial condition.

We now give examples of common non-pathogenic types.

Zygomycetes: Mucor mucedo (and other species of Mucor).—This form occurs on damp bread, horse dung, and other organic substrata. To the naked eye it appears as a white or smoky mould composed of fine filamentous usually non-septate hyphæ spreading over the substratum. Here and there arise erect hyphæ which in a saturated atmosphere may attain a length of several inches, but which are very much shorter in ordinary air. Each erect hypha ends in a spherical sporangium whose protoplasm is separated off from that of the supporting hypha by a transverse wall, which bulges greatly into the cavity of the sporangium and forms the so-called columella. The protoplasm of the sporangium divides into many masses, each of which acquires a cell-wall and is then a spore. The spores escape by the rupture of the wall of the sporangium. (The needle-like bodies often seen outside the wall of the sporangium are crystals of calcium oxalate.) The less frequent sexual method of reproduction and the formation of the zygospore has already been described. The infrequency of the sexual mode of reproduction is due partly to the fact that the individual plants are sexually differentiated and might be termed male and female. Zygospore and asexual spore alike

germinate to produce a new mycelium. In rich culture media or old cultures the mycelium may become septate. Cultivated under water some species (including *Chlamydomucor racemosus*) enter into an oidial condition.

Ascomycetes: (1) **Aspergillus herbariorum** (=**A. niger**).—This, with other varieties of the same group, is of frequent occurrence, especially on dead vegetable matter. It grows readily on gelatin and, to the naked eye, consists of a mass of filaments which microscopically are seen to form a septate branching mycelium. Two forms of reproduction occur, the variety depending largely on the nutrition of the plant. The less common form is effected by means of structures known as ascocarps, which owe their formation to a sexual process. From a mycelial branch there arises a hypha which becomes specially coiled and transversely septate at its end. From the base of the lowest coil of the spiral two or three hyphæ grow up towards its apex, where one of these fuses with the coiled hypha and represents the male organ. The others by branching copiously produce a mass of closely woven hyphæ forming a closed wall to this structure, which is the ascocarp referred to. Within it numerous asci arise as the ultimate ramifications of branches given off by the central coiled hypha. Inside each ascus eight ascospores are produced. Ultimately all the structures lying within the ascocarps, save the spores, undergo disintegration, so that the mature ascocarp consists of a small hollow sphere within which lie the loose spores. These latter are ultimately freed by the decay of the wall of the ascocarp and develop into new individuals. The commonest method of reproduction is by the formation of spores in the form of conidia, which are clearly of non-sexual origin. A filament grows out, and at its termination a rounded swelling is formed on which a series of little finger-like processes called sterigmata are perched. At the free end of each of these, rows of oval conidia are successively abstricted. Each conidium, on becoming free, can give rise to a new individual, just as can an ascospore.

(2) **Penicillium crustaceum** (=**Penicillium glaucum**).—This is perhaps a composite species and is the most common of all fungi met with in bacteriological work. It is the common green cheese mould, and its extraordinary versatility and powers of resistance make its spores practically omnipresent. The mycelium is like that of the *Aspergillus*. Ascocarp formation takes place, but the commonest mode of reproduction is by the conidia. A filament (the conidiophore) grows out, and at its end frays out into a pencil of finger-like branches. On the point of each of these a peg-like sterigma is developed. On the end of this a row of oval conidia is successively cut off; these break off and can give rise to new individuals.

(3) **Saccharomyces or Yeasts** (**Torula, Mycoderma**).—These organisms have been subjected to much investigation in consequence of their economic importance in brewing and baking. They occur in nature chiefly in connection with fruits, such as the grape, which contain fermentable sugars. They consist of round or oval cells, 3 to 5 μ in longest diameter, and under ordinary conditions reproduce themselves by budding, in which process a portion of the cell protrudes, increases in size, and finally becomes separated from the parent cell so as to form a new individual. In a number of other fungi belonging to the various groups, the conidium, when cultivated in a liquid, has the power of budding off conidia which behave in like manner; such fungi, therefore, have a yeast-like stage in their life-history. Under certain conditions of

moisture and oxygen supply, endogenous sporulation occurs. As the spores produced are definite in number—two in some species and four in others—the sporangium is an ascus and *Saccharomyces* is a degenerate ascomycete. While in yeasts generally the oval cell represents the vegetative unit, in certain species elongated tube-like bodies may be formed which suggest an attempt at hyphal formation. In *Saccharomyces mycoderma*, the vegetative cells are so elongated and linked as to form a kind of simplified mycelium.

Fungi imperfecti: Oospora lactis (Fres.) (**=Oidium lactis**).—This is a common fungus in sour milk and sour bread, and can easily be cultivated on gelatin, where the colonies consist of short and fine septate filaments radiating from a centre. Here and there the hyphæ are divided, especially at the ends, into short oval or cylindrical segments, termed oidia, which act as spores. No other method of reproduction is known.

It is probable that near to, or in, this unnatural genus *Oospora*, should be placed the fungi causing tinea and favus. Many other fungi associated with disease processes in human beings are to be grouped among the *Fungi imperfecti*.

TINEA. FAVUS.

In dealing with the common fungoid infections of the skin, it is only possible here to give a short account of the methods employed in the investigation and of the more common types of fungi isolated.

Methods.—For ordinary purposes of diagnosis it is usual to place the epidermic scales or hairs in a solution of 7 grms. of potash in 100 c.c. of water (Adamson) or in liq. potassæ (B.P.), to heat for a few seconds and to examine under a cover-glass. For permanent stained preparations Sabouraud recommends that the fat should first be removed by means of chloroform from the material, which is then placed in formic acid and warmed for two or three minutes till the fluid boils. The acid is removed by washing in distilled water and the preparation stained for a minute with Sahli's blue, which has the following composition: Distilled water, forty parts; saturated aqueous solution of methylene-blue, twenty-four parts; 5 per cent. solution of borax, sixteen parts; it is then washed, dehydrated in absolute alcohol, cleared in xylol, and mounted in balsam.

The glucose and maltose media of Sabouraud (p. 53) constitute the best means of isolating skin fungi, as by these not only are the most characteristic growths obtained, but there is a certain degree of inhibition of the omnipresent skin cocci. Where, as in tinea circinata, there is a vesicular or pustular lesion, the contents are squeezed out and transferred with a platinum needle to the medium. Where there is a skin scurf, the squames may be scraped off on to a sterile slide from which tubes may be infected. Where hairs are to be dealt with, these may be picked out on to a sterile slide, their roots cut off with a hot needle and planted in the medium. In certain hair affections, especially in animals, the parasite is specially abundant in the aerial part of the hair, so that portions of this, as well as the radical, ought to be used. It is often advisable, especially in pustular conditions and in favus, to place the hair in absolute alcohol for two minutes, to allow to dry and then plant on the medium.

Microspora.—The small-spored ringworm parasites are responsible for a large proportion of the ringworms of the scalp occurring in children, and only occasionally cause affections of the other parts of the body. In the initial lesion in the epidermis a fine mycelium, 1–5 μ in diameter, may be observed, composed of rectangular elements, demonstrable in stained preparations. This mycelium penetrates into the hairs where they emerge from their sheaths, and grows up and down in them. When an infected hair is examined, it is found to be encased with a mass of spores which have the characters of an

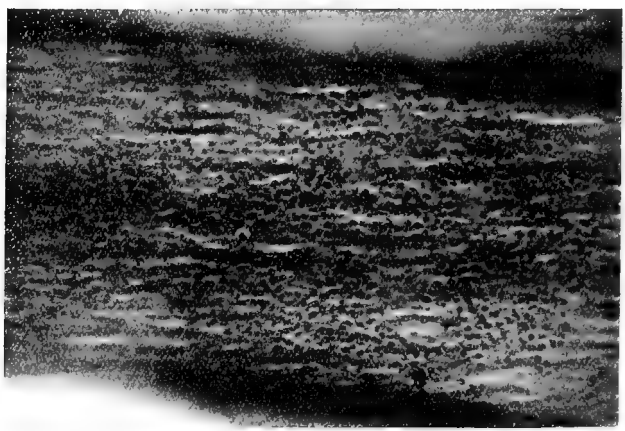

FIG. 163.[1]—Hair infected with Microsporon audouïni. Photograph of unstained preparation. ×500.

irregular mosaic, the elements being frequently crushed together in polygonal forms and showing no tendency to an arrangement in rows. These spores are about 2 μ in diameter, but in potash preparations may appear larger,—up to 5 μ. According to Sabouraud, the appearance on the hair results from intracapillary mycelial threads breaking out at numerous points on the surface and there undergoing irregular longitudinal and transverse splitting, to form the spores. The mycelium can be demonstrated by mounting the hair in 7 per cent. potash solution and disengaging the adherent and obscuring spores by gently rubbing the hair between the slide and the cover-glass. The species most commonly present is the *Microsporon audouïni*.

[1] For Figs. 163–169, 174, we are indebted to the kindness of Dr. R. Cranston Low.

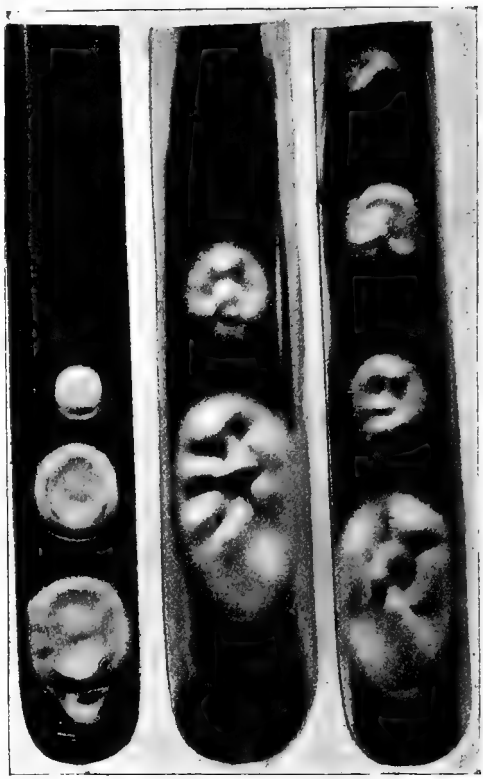
(Fig. 163), and a number of allied species have been isolated in the dog, the cat, and the horse, and these are of importance from the frequent infection of man from such animal sources. Other species, *e.g.*, *M. velveticum*, *M. umbonatum*, and *M. tardum*, presenting cultural differences, have been observed in man.

Trichophyta. — These fungi, which constitute the large-spored ringworms, are associated with ringworm of the scalp, with the various manifestations found in the beard, and with the conditions occurring on the smooth parts of the body and in the nails. They are characterised by the fact that the mycelium, wherever observed,—whether in epithelial squames, in pus, or within a hair—consists of chains of oval or rectangular spore-like bodies (Fig. 166). These in the largest forms are from 5–8 μ in diameter, but smaller forms approaching the size of the spores in microspora also exist. There is thus not the same differentiation between mycelium and spore formation seen in the microspora, nor does the irregular mosaic appearance of the spores in the latter come into evidence. There is, however, the same primary affection of the superficial epithelium, and in hairy parts the invasion of the hair where it emerges from its sheath.

FIG. 164.—Microsporon audouïni on Sabouraud's maltose agar.

In certain species there is a tendency for the parasite to invade the follicle by growing down between the hair and its sheath for a considerable period before the hair itself is invaded, —the so-called *Trichophyton ectothrix*. A great number of trichophyta presenting different cultural characteristics have been isolated. These are associated with difference in site of election and in method of spread in different parts of the body.

There is evidence that certain varieties are more common in some countries than in others; for instance, in France *Trichophyton acuminatum* is the more common, whereas in Scotland *Trichophyton crateriforme* (variety *flavum*) (Fig. 165 *a*) is the



a *b* *b*

FIG. 165.—*a*, Trichophyton crateriforme. *b*, Trichophyton rosaceum. Sabouraud's medium.

most frequent cause of large-spored ringworm of the scalp, and *Trichophyton rosaceum* (Fig. 165 *b*) of ringworm of the beard. In France another coloured variety—*Trichophyton violaceum*—is of common occurrence. Similar organisms have been described in the lower animals, such as the horse, calf,

and dog, and the infection of man from such sources is relatively frequent.

The pathological lesions produced by the microspora and trichophyta are similar, though those of the latter are the more severe. In each case there is primarily a premature detachment of epithelial squames with subjacent inflammation in the corium, frequently followed by a slight hyperkeratosis, especially

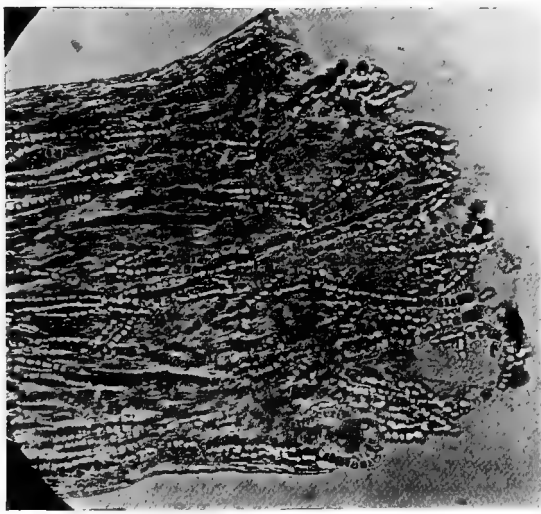


FIG. 166.—Hair infected with large-spored ringworm. Photograph of unstained preparation. ×500.

Note.—The sizes of the spores in Figs. 163 and 166 are not comparable, as in photographs of such thick preparations it is impossible to sharply focus the outlines.

marked around and within the hair sheaths. Follicular pustules are also common and in the most severe trichophytal cases a granulomatous condition (kerion) of the true skin, with relatively massive follicular suppuration, occurs.

Achoria.—These organisms are responsible for the various clinical manifestations grouped under the name of favus which affect both the hairy and smooth parts of the body. The characteristic of these is the development of round sulphur-yellow discs (*scutula*) each with a depression in the middle which in hairy parts often corresponds to the position of a hair follicle.

These discs really consist of dense masses of fungoid growth (Fig. 169). The feature is an initial vigorous invasion of the epithelial squames, sometimes accompanied by an intra-epidermic, very often circumpilary, suppuration. As in the conditions previously described, the hair becomes invaded, the shaft being especially affected, but the hair infection is of subsidiary importance. The feature of the affection is the destruction of skin structures (*e.g.*, hair follicles), this leading, when recovery takes place, to the affected part assuming a cicatricial character. This is apparently consequent on a pressure atrophy of the tissues brought about by the formation of the scutula. Sometimes a granulomatous affection of the skin is observed, which

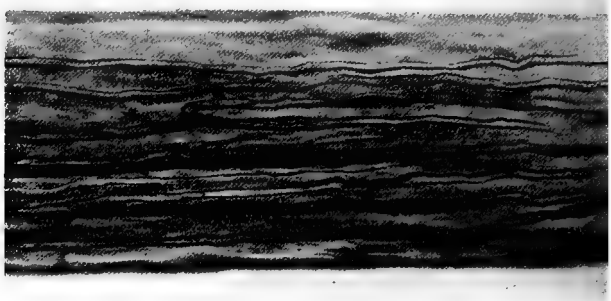

FIG. 167.—Favus hair showing air channels left by mycelium. ×300.

may be due to secondary infections. Preparations from the crusts (Fig. 169) show the presence of spores and mycelial threads, whose elements vary much in size and shape, but which are generally larger than those of the trichophyta. The affection of the hairs is severe, and the track of the mycelium is often marked by the presence of comparatively large air bubbles (Fig. 167). The commonest fungus present is the *Achorion schönleinii* (Fig. 168 *a*), but a great number of varieties occur, and again the lower animals (fowl, mouse, dog, cat (Fig. 168 *c*)) are affected. These can be readily cultivated on Sabouraud's media.

Of the less common skin fungi, *Epidermophyton inguinale*, found in eczema marginatum, deserves mention. In preparations of the epithelial scales the organism presents itself in complex undulating threads consisting of short elements 4 to 5 μ broad and 4 to 12 μ long. Its characters mark it off from the

organisms described. The hairs in the diseased area remain unaffected, but the organism is closely allied to the trichophyta, though it is not so easily cultured. Infection experiments with cultures have hitherto failed.

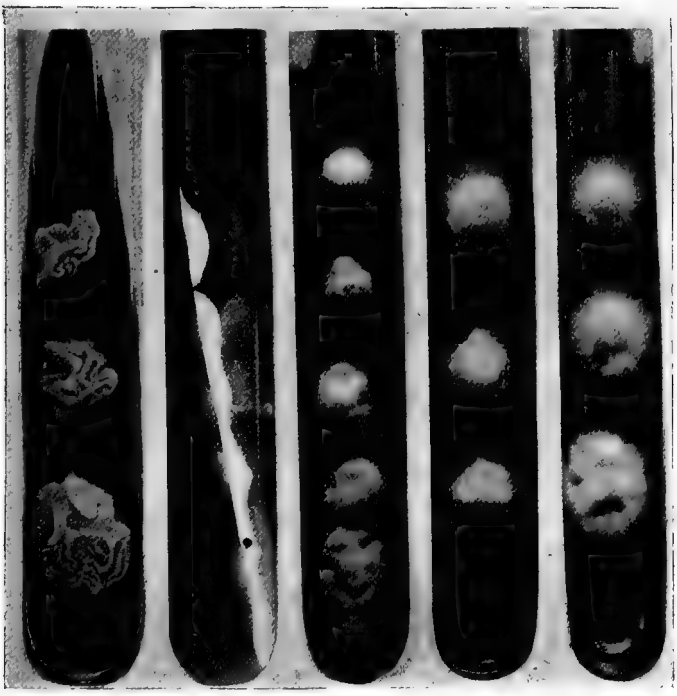

FIG. 168.—*a*, Photograph of drawing of Achorion schönleinii on Sabouraud's maltose agar. *c*, Photographs of cultures of Achorion quinckeanum. (The central culture of *c* was isolated from a cat, and the two side tubes from a man infected from it.) *b*, Side view to show elevation of growth.

It is impossible for us to describe in detail the botanical characters presented in cultures by the three groups of parasitic skin fungi, and we can only mention certain commonly occurring characters. In all there is a free production of a septate mycelium, and usually, by a lateral budding from the hyphæ or by the breaking up of the protoplasm of the thread, there is the

formation of bodies resembling those described as spores which occur in affected tissues. This spore formation often shows a tendency to occur specially at the termination of filaments. Sometimes in the course of a filament an element enlarges and from it new mycelia sprout, the whole resembling chlamydospore formation. Sometimes, especially in the microspora and the achoria, large fusiform elements divided by transverse septa are observed, which suggest conidia formation. Curious spiral

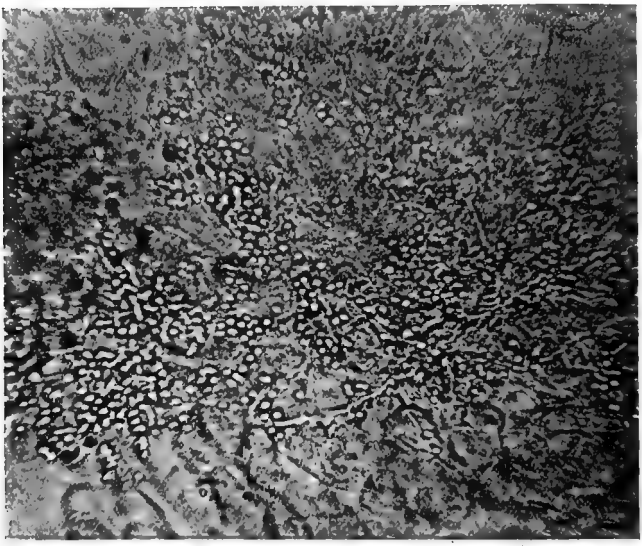

FIG. 169.—Photograph of drawing of scraping from favus scutula, showing spores and mycelium. Unstained. ×250.

elements whose significance is unknown are also frequently seen.

We cannot enter into an elaborate description of the naked-eye characters of the various ringworm and favus fungi, and for these the reader must be referred to such works as those of Sabouraud. The characters vary very much with the medium employed, and hence in any comparative study it is of great importance that the same medium should be used, and it is even necessary that a large bulk of a medium should be made up at once so as to be available for an extended study.

On Sabouraud's media most of the fungi at the commencement of their growth appear as white fluffy or felted button-like colonies on the surface of the medium, and as growth proceeds a great variety of differentiating characters emerge. Thus the organism may tend to spread in a fairly thin layer over the medium and sometimes may present the appearance of successive concentric rings of growth; on the other hand the colony may be heaped up in the centre as a projecting knob, or there may be a central depression round which the heaping up may occur. Sometimes there are ridges or folds radiating from the centre of the colony, often presenting a geometrical arrangement but sometimes having an irregularly convoluted appearance. The surface may have a general woolly appearance or may give the impression of being covered with fine powder. Sometimes the surface formation is moist and slimy-looking. These appearances are exemplified in Figs. 164, 165, 168. When colour is produced it develops with age. An important point is the occurrence of pleomorphism. Thus a sub-culture frequently presents characters different from those of the parent growth, or on a coloured colony colourless points may appear which may maintain the non-pigmented character when sub-cultured. The evidence at present is that these are cases of true pleomorphism and are not due to contaminations. On media presenting large surfaces the colonies assume a correspondingly large size and growth usually goes on until the whole medium is exhausted.

Strickler has prepared a vaccine for treating tinea of the scalp by disintegrating twenty-four-day cultures of tinea in a mortar with pure sodium chloride crystals and dissolving the magma in water to form a solution of normal saline strength; to 500 c.c. are added 10 c.c. of chloroform, and the vaccine is killed by heating for an hour at 60° C. Five doses of from 0·5 to 2 c.c. are injected between the shoulders at six-day intervals.

Thrush (German, *Spoor*; French, *Muguet*).

This condition, which is most common in children, chiefly affects the tongue and fauces, and may extend into the œsophagus. It is characterised by white patches largely composed of fungoid growth, which cause slight erythema and catarrh of the subjacent epithelium. A similar condition may occur in the vagina, and a few cases of generalised affection with abscesses or tubercle-like lesions in the solid organs, *e.g.*, the lungs, have been recorded. The organism closely resembles the *Oospora* (*Oidium*) *lactis* (*vide* p. 535), very frequently found in milk, and has been called *Oidium albicans* or *Monilia candida*. It occurs in two chief

varieties—a large-spored and a small-spored form, the former being the more frequent. Both in the tissues and in cultures the chief elements are double-contoured, septate mycelial threads,—the elements being of varying sizes,—and round or oval spores (in the large-spored type 5–6 μ long and 4 μ broad). The fungus grows readily on artificial media, especially those containing beerwort (p. 53), and while some varieties liquefy gelatin, others do not. In the case of the latter, the superficial colonies on gelatin are granular with peripheral feathery extensions, while the deep colonies are rounder and more circumscribed. The colour is white or slightly red, and the cultures have a sourish alcoholic smell due to the production of aldehyde, alcohol, and acetic acid; glucose, lævulose, and maltose are slowly fermented, but the fermentation reactions differ in different species of moniliæ. On ordinary media, mycelium and spore production are seen, the former being especially marked in deep colonies. Chlamydospore formation is also stated to occur, and from such elements on a mycelium, free conidia formation takes place.

Aspergillosis.

In 1856, Virchow recorded several cases of affection of the lungs by aspergilli, and a number of similar cases have since been described; usually there has existed some other disease in the body, and frequently the lung has also been the site of tuberculosis. The appearances presented are those of small grey nodules, composed of necrotic material and leucocytes, breaking down to form cavities associated with areas of broncho-pneumonia, and frequently also with fairly widespread odourless necrosis of the lung. Masses of fructifying mycelia are present in the cavities and extend into surrounding bronchioles and air cells. The condition has usually been discovered *post mortem*, but in certain cases the fungus has been observed in the sputum during life, and it is probable that a lung condition of this kind can be recovered from. A similar affection occurs in birds. It is probable that infection arises from inhalation. The variety of organism chiefly present is the *Aspergillus fumigatus* (cf. p. 534), which on artificial media gives a greenish-blue colour resembling that of the *Penicillium crustaceum*. Its optimum temperature is that of blood heat.

Infections with aspergilli also occur in the external ear as a chronic pustular condition of the epithelium, and aspergillary colonies are also from time to time observed on abrasions of the cornea.

Sporotrichosis.

In 1898, Schenk, in America, described a case of chronic subcutaneous abscesses associated with a fungus belonging to the sporotricha, and during recent years the organism has been isolated from a great many granulomatous conditions occurring in various parts of the world. Most of the cases have been characterised by somewhat heteromorphic and indolent granulomatous lesions in the skin, resembling those of tuberculosis and syphilis. The initial lesion is at the site of some slight abrasion, and it is followed by a succession of, usually small, granulomata, whose distribution indicates a lymphatic spread. There is little tendency to spontaneous cure. Apart from the skin, cases have been recorded of lesions in the pharynx, larynx, muscle, bone, and synovial membrane, and both in man and in animals (dogs, rats) generalised infections of the serous cavities and solid organs have been observed. The lesions are of a diffuse granulomatous character, and at first consist of young connective-tissue elements and plasma cells with little leucocytic exudation. Later, many fibroblasts develop, embedded in a fibrinous-like exudate. Diffuse degeneration and necrosis occur and also leucocytic emigration with the formation of abscesses, at first of microscopic size. When the skin is involved, ulceration results. In certain cases abscess formation is more marked.

Direct examination of the pus may reveal the presence of oval, highly refractile spores, 3–4 μ long and 1·6–3 μ broad, and these may be demonstrated both free and in the granulomatous cells, in films and sections stained by ordinary aniline dyes; they are Gram-positive. Mycelial formation does not occur in the tissues, except occasionally in the most superficial parts of an ulcerating lesion. If a drop of pus be placed on the glass of an agar slope just above the condensation water, the sprouting of a mycelium from the spores may be directly observed with the microscope. The organism, which is generally known as the *Sporotrichon beurmanni*, grows readily on any ordinary medium (gelatin, agar, potato), but is best studied on Sabouraud's medium. Two sets of media should be inoculated—one incubated at 37° C. and the other at room temperature. On the latter, after about forty-eight hours, somewhat fluffy, snowflake-like, white points appear which gradually become brown, and when growing in mass present a heaped-up convoluted growth. The morphology of the organism is best studied in hanging-drop preparations made with agar. From a spore a mycelial thread about 1 μ in thickness, irregularly septate, and often containing

fine granules, sprouts off. Lateral branches arise and fresh spore formation is soon observed. These usually develop in whorls round a filament (Fig. 170), but sometimes the process occurs all along a filament. Sometimes, in the course of a filament, large circular elements, 5–6 μ in diameter, resembling the zygospores of Mucoraceæ are seen, and these sometimes contain groups of spore-like bodies. The free growth of the organism depends on conditions of moisture and temperature, and where

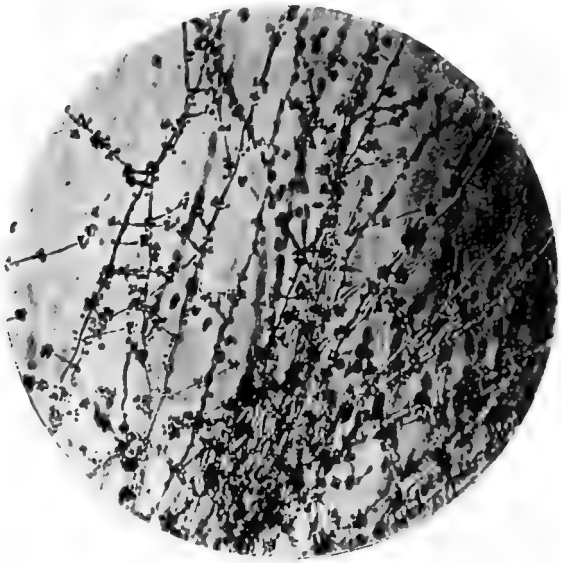

FIG. 170.—Edge of living colony of Sporotrichon beurmanni on agar hanging-drop, five days at 22° C. ×200.

these are unfavourable, instead of mycelial formation being observed, the spores may enlarge to three or four times their ordinary size and then give off circles of fresh spores (Fig. 171). Under a low power of the microscope, mycelial colonies have a stellate appearance with a very freely spiked edge. The organism manifests considerable vitality under saprophytic conditions, as might be expected from the widespread distribution in nature of allied members of the group and even, it is said, of the *Sporotrichon beurmanni*. The organism in artificial cultures is pathogenic when injected subcutaneously in mice, rats, dogs,

etc., granulomatous lesions identical with those of the natural disease being produced.

Sporotrichosis in man has probably often been confused with the manifestations of syphilis, as the condition readily yields to the administration of potassium iodide. In horses, certain cases presenting the characters of epizootic lymphangitis have been found to be associated with an organism indistinguishable from the *Sporotrichon beurmanni*.

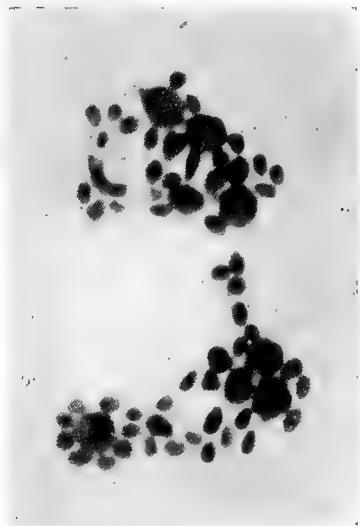

FIG. 171.—Film from agar culture of Sporotrichon beurmanni grown at 37° C. for ten days. Gram's stain. ×1025. Note large circular bodies with spores sprouting off; also a few sausage-shaped elements.

BLASTOMYCOSIS.

In pathological literature there are recorded a very large number of usually isolated cases presenting the characters of granulomata or of chronic suppurations, in connection with which the presence of yeast-like bodies has been observed, and from which cultures of these have been obtained. The relation of the organism isolated to the known types of fungi is largely undetermined. In the tissues the organisms usually appear as single double-contoured cells which multiply by budding or by a process resembling endogenous sporulation, while in artificial cultures, although similar appearances may be seen, a tendency to mycelium formation is frequently observed. The term blastomyces, which may be taken as synonymous with yeast, finds no place nor has it any specific significance in modern descriptive fungology, for in vastly differing species yeast-like elements occur representing stages in development. From their tendency to produce mycelia, the organisms concerned in the so-called blastomycosis probably approach most nearly to the oidia (oospora), so that oidiomycosis might be a more scientific denomination of the diseases in question.

While organisms of this group have been isolated from many conditions, for example rabies and malignant tumours, in which there is no evidence that they play an etiological rôle, there is no doubt that they can multiply and originate pathological changes in the animal body. An example of this is seen in Fig. 172, taken from the kidney of a rabbit which was inoculated subcutaneously with an organism isolated from the sputum of a human case of obscure granuloma of the lung, associated with a suppurative condition in the kidney, and the presence of similar organisms in the urine. In this case the appearances of the organisms in the tissues corresponded to those seen in cultures. In the conditions about to be described, and of which we have had no personal experience, difficulties present themselves in that the supposed causal agent appears in the tissues in the form of a peculiar round double-contoured cell (Fig. 173) not exactly reproducible in artificial cultures. The appearances of these cells are rather

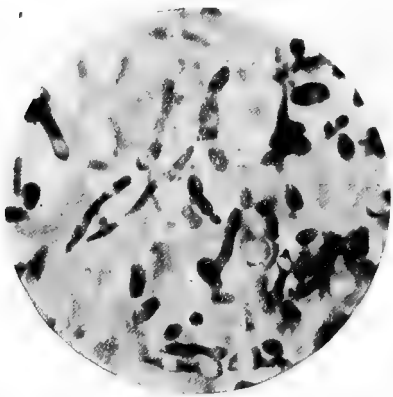

FIG. 172.—Growth of blastomyces in kidney of rabbit infected from human case (see text). ×1000.

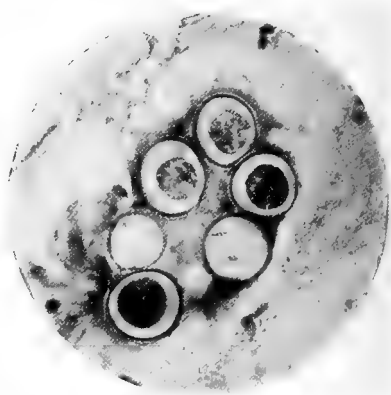

FIG. 173.—Double-contoured bodies in tissues from one of Rixford and Gilchrist's cases. ×500.[1]

[1] For the tissue from which this preparation was made we are indebted to Dr. Rixford.

suggestive of protozoal characteristics and, while a mycelial formation is stated to have been observed to originate from them, we consider that their nature is not yet fully elucidated. They have been observed in two disease manifestations which we may now describe. The first of these is the blastomycetic dermatitis, widely studied in America and especially in Chicago. The disease may arise in any part of the skin and frequently follows a slight wound. The development of a sluggish papule, becoming pustular and ulcerative, is followed by a slowly extending granular and papillomatous appearance, with irregularly distributed pustule formation, and surrounded by a reddened areola containing numerous miliary abscesses. Areas of this kind, several inches in diameter, may slowly develop. These may heal at one margin and extend widely at another. The process may go on for years, and various, it may be distant, parts of the skin may become successively affected. In the great majority of cases no general disturbance occurs. Microscopically, in the fully advanced stage, the picture is that of an irregular epithelial proliferation and hyperkeratosis with superficial papillomatous excrescences, and more deeply of a similar irregular and free epithelial proliferation taking place in a granulomatous condition of the cutis. Special features are the development of minute pustules, partly intra-epithelial, partly in the corium, and the formation of giant cells, probably of epithelial origin. In the pus, organisms presently to be described are found. The characteristics of blastomycetic dermatitis are its chronic nature and its restriction to the skin.

A closely allied condition is that described by Wernicke in South America and by Rixford and Gilchrist in California. In the first described cases attention was directed to the appearance of suppurative conditions in the lungs. A skin lesion also occurs, characterised by subcutaneous abscesses or granulomata leading to ulceration with epithelial hyperplasia. This may be the primary manifestation of the disease, but the internal organs become affected with chronic suppurative processes or granulomata, and death occurs. Cases belonging to the same class are also recorded where subcutaneous nodules, consisting of myxomatous connective tissue, have been observed associated with the occurrence of suppurations in the internal organs. The cases of generalised infection were at first attributed to protozoa. The direct observation, under the microscope, of the growth of a mycelium from the protozoon-like body is the evidence adduced for the fungoid nature

of the organism and led to its being denominated *oidium coccidioides.*

The organisms isolated from these varying lesions are evidently all closely allied, although probably not identical. In blastomycetic dermatitis the organisms are present chiefly in the abscesses in the corium and to a less extent in the more superficial suppurations, and can be demonstrated by mounting the pus in 30 per cent. caustic potash solution. They are spherical in form, 8 to 10 μ in diameter, and appear singly, in pairs, or less frequently in larger groups (Fig. 173). There is a central protoplasm without a nucleus, separated by a delicate membrane from a surrounding clear space, and the whole is enclosed in a highly refractile, double-contoured capsule. Budding is frequently seen. The organisms stain with hæmatoxylin and with aniline dyes and are Gram-positive, the reaction of the capsule being variable. The organisms present in the generalised infections are much more numerous in the tissues and attain the size of 35 μ. In these also there are appearances in the protoplasm which suggest endogenous sporulation. The facility with which the fungi have been cultivated varies in different cases, but growth can usually be readily obtained at room temperature or at 37° C. on ordinary media, but preferably on Sabouraud's maltose medium, especially when this is made slightly acid. Growth appears in from two to seven days, and the characteristics vary. In some cases moist, paste-like colonies develop, in others the surface appears crumpled, and sometimes it is dry and powdery. These differences are associated with differences in the degree of mycelial formation, in the extent of the ingrowth of the organism into the medium, and in the presence or absence of aerial conidia. The effects of the different varieties differ. Glucose and maltose are usually

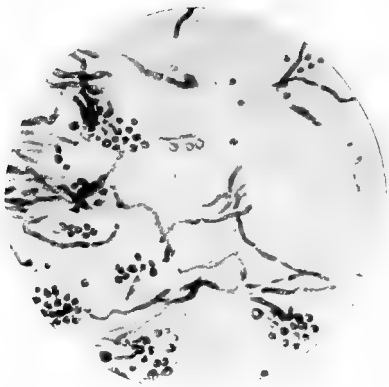

FIG. 174.—Microsporon furfur; scraping from skin. Stained by Gram. ×1000.

fermented; gelatin is ordinarily not liquefied; and indol formation is uncommon. In cultures, the budding seen in the tissues is also observed, and there is a varying amount of formation of segmented and branching hyphæ, this being particularly well marked in certain cases and giving rise to a definite mycelium. Somewhat slender aerial hyphæ sometimes occur which may form lateral spherical conidia, and sometimes terminal bodies resembling ascospores. The elements in cultures resembling those seen in the tissues frequently also possess a double-contoured capsule.

A considerable number of the organisms isolated are pathogenic for animals. Abscesses follow subcutaneous inoculation in guinea-pigs, rabbits, and mice, and death may result. Intravenous injection may result in a fatal pulmonary infection; intraperitoneal infection is often without result.

Microsporon Furfur.

This is the organism associated with pityriasis versicolor. The condition, which is very widespread all over the world, occurring often in phthisical patients, is not looked upon as a disease of the skin, but is due to the saprophytic growth of the microsporon on the skin surface. The organism can be demonstrated in scrapings from the lesion, either examined in potash solution or in films stained by, for example, Gram's method. The organism consists of an irregularly contoured crumpled mycelium in segments from ·7–13 μ long and 3–4 μ broad. Associated with this, there are irregular groups of double-contoured spore-like bodies from 4–7 μ in diameter (Fig. 174). Nothing further is known regarding the organism, as most attempts at cultivation have had a negative result, and even where cultures are said to have been obtained it has been impossible to secure continued growth.

CHAPTER XXII.

IMMUNITY.

Introductory.—By immunity is meant non-susceptibility to a given disease or to a given organism, either under natural conditions or under conditions experimentally produced. The term is also used in relation to the toxins of an organism. Immunity may be possessed by an animal naturally, and is then usually called *natural* immunity, or it may be *acquired* by an animal, either by its passing through an attack of the disease, or by means of artificial inoculation. It is to be noted that man and the lower animals may be exempt from certain diseases under natural conditions, and yet the causal organisms of these diseases may produce pathogenic effects when injected in sufficient quantity. Immunity is, in fact, of very varying degrees, and accordingly the use of the term has a relative significance. This is not only true of infection by bacteria, but of toxins also —when the resistance of an animal to these is of high degree, the resistance may in certain cases be overcome by a very large dose of the toxic agent. On the other hand, even in cases where the natural powers of resistance are high, these can be still further exalted by artificial means—that is, the natural immunity may be artificially intensified.

Acquired Immunity in the Human Subject.—The following facts are supplied by a study of the natural diseases which affect the human subject. First, in the case of certain diseases, one attack protects against another for many years, sometimes practically for a lifetime, *e.g.*, smallpox, typhoid, scarlet fever, etc. Secondly, in the case of other diseases, *e.g.*, erysipelas, diphtheria, influenza, and pneumonia, a patient may suffer from several attacks. In the case of the diseases of the second group, however, experimental research has shown that in many of them a certain degree of immunity does follow; and, though we cannot definitely state it as a universal law, it must be considered highly probable that the passing through an attack

of an acute disease confers immunity for a longer or shorter period. The immunity is not, however, to be regarded as the result of the disease *per se*, but of the bacterial products introduced into the system; as will be shown below, by suitable gradation of the doses of such products, or by the use of weakened toxins, a high degree of immunity may be attained without the occurrence of any symptoms whatever. It has been found in the case of diphtheria, typhoid, cholera, pneumonia, etc., that in the course of the disease certain substances appear in the blood, which are antagonistic either to the toxin or to the vital activity of the organism. In such cases a process of immunisation would appear to be going on during the progress of the disease, and when this immunisation has reached a certain height, the disease naturally comes to an end. It cannot, however, be said as yet that such antagonistic substances are developed in all cases; although the results already obtained make this probable.

The facts known regarding vaccination and smallpox exemplify another principle. We may take it as practically proved that vaccinia is variola or smallpox in the cow, and that when vaccination is performed, the patient is inoculated with a modified variola (*vide* Smallpox in Appendix). Vaccination produces certain pathogenic effects which are of trifling degree as compared with those of smallpox, and we find that the degree of protection is less complete and lasts a shorter time than that produced by the natural disease. Again, inoculation with lymph from a smallpox pustule produces a form of smallpox less severe than the natural disease but a much more severe condition than that produced by vaccination, and it is found that the degree of protection or immunity resulting occupies an intermediate position.

Artificial Immunity.

Varieties.—According to the means by which it is produced, immunity may be said to be of two kinds, to which the terms *active* and *passive* are generally applied, or we may speak of immunity *directly*, or *indirectly*, *produced*. We shall first give an account of the established facts, and afterwards discuss some of the theories which have been brought forward in explanation of these facts.

Active immunity is obtained by (*a*) injections of the organisms either in an attenuated condition or in sub-lethal doses, or (*b*) by sub-lethal doses of their products, *i.e.*, of their "toxins," the word being used in the widest sense. By repeated injections

at suitable intervals the dose of organisms or of the products can be gradually increased; or, what practically amounts to the same, an organism of greater virulence or a toxin of greater strength may be used. The establishment of immunity is attended by the appearance of *anti-substances* in the serum, and the molecules of the bacteria or toxins which lead to the development of these are called *antigens*. Such methods constitute the means of *preventive inoculation* or *vaccination*. Immunity of this kind is comparatively slowly produced and lasts a considerable time, the duration varying in different cases. The principles of vaccination have within recent years been extended by Wright to the *treatment* of disease.

Passive immunity depends upon the fact that if an animal be immunised to a very high degree by the previous method, its serum may have distinctly antagonistic or neutralising effects when injected into another animal along with the organisms, or with their products, as the case may be; that is, the anti-substances developed by active immunisation may be transferred to a fresh animal. Such a serum, generally known as an *anti-serum*, may exert its effects if introduced into an animal at the same time as infection occurs or even a short time afterwards; it can, therefore, be employed as a *curative* agent. The serum is also preventive, *i.e.*, protects an animal from subsequent infection, but the immunity thus conferred lasts a comparatively short time. These facts form the basis of *serum therapeutics*. When such a serum has the power of neutralising a toxin it is called *antitoxic*; when, with little or no antitoxic power, it protects against the living bacterium in a virulent condition, it is called *antimicrobic* or *antibacterial* (*vide infra*).

In the accompanying table a sketch of the chief methods by which an immunity may be artificially produced is given. It has been arranged merely for purposes of convenience and to aid subsequent description; the principles underlying all the methods are the same.

ARTIFICIAL IMMUNITY.

A. Active immunity—*i.e.*, produced in an animal by an injection, or by a series of injections, of non-lethal doses of an organism or its toxins.

1. *By injection of the living organisms.*

(*a*) Attenuated in various ways. Examples :—

(1) By growing in the presence of oxygen, or in a current of air.

(2) By passing through the tissues of one species of animal (becomes attenuated for another species).
(3) By growing at abnormal temperatures, etc.
(4) By growing in the presence of weak antiseptics, or by injecting the latter along with the organism, etc.

(*b*) In a virulent condition, in non-lethal doses.

2. *By injection of the dead organisms.*
3. *By injection of the dead organisms, "sensitised" by an anti-serum.*
4. *By injection of filtered bacterial cultures,* i.e., *toxins ; or of substances derived from such filtrates.*

These methods may also be combined in various ways.

B. Passive immunity—*i.e.*, produced in one animal by injection of the serum of another animal highly immunised by the methods of A.

1. *By antitoxic serum, i.e.*, the serum of an animal highly immunised against a particular toxin.
2. *By antibacterial serum, i.e.*, the serum of an animal highly immunised against a particular bacterium in the living and virulent condition.

Methods of producing Active Immunity.

1. **By Living Cultures.**—(*a*) *Attenuated.*—In the earlier work on immunity in the case of anthrax, chicken cholera, swine plague, etc., the investigators had to deal with organisms of high virulence, which had accordingly to be reduced before the organisms could be injected in the living state. It is now found most convenient as a rule to start the process of active immunisation with the injection of dead cultures. The principle is the same as that of vaccination, and both attenuated cultures and also the dead cultures used for injection are often spoken of as *vaccines.* The virulence of an organism may be diminished in various ways, of which the following examples may be given :—

(1) In the first place, practically every organism, when cultivated for some time outside the body, loses its virulence to a greater or less degree, and in the case of some this is very marked indeed, *e.g.*, the pneumococcus. Pasteur found in the case of chicken cholera, that when cultures were kept for a time in ordinary conditions, they gradually lost their virulence, and that when sub-

cultures were made the diminished virulence persisted. Such attenuated cultures could be used for protective inoculation. He considered the loss of virulence to be due to the action of the oxygen of the air, as he found that in tubes sealed in the absence of oxygen the virulence was not lost. Haffkine attenuated cultures of the cholera spirillum by growing them in a current of air (p. 473).

(2) The virulence of an organism for a particular animal may be lessened by passing the organism through the body of another animal. Duguid and Burdon Sanderson found that the virulence of the anthrax bacillus for bovine animals was lessened by its being passed through guinea-pigs, the disease produced in the ox by inoculation from the guinea-pig being a non-fatal one. This discovery was confirmed by Greenfield, who showed that the bacilli cultivated from guinea-pigs preserved their property in cultures, and could therefore be used for protective inoculation of cattle. A similar principle was applied in the case of swine plague by Pasteur, who found that if the organism producing this disease was inoculated from rabbit to rabbit, its virulence was increased for rabbits but was diminished for pigs. The method of vaccination against smallpox depends upon the same principle. There is also evidence to show that the virulence of the tubercle bacillus becomes modified according to its host, being often diminished for other animals.

(3) Many organisms become diminished in virulence when grown at an abnormally high temperature. The method of Pasteur, already described (p. 347), for producing immunity in sheep against anthrax bacilli, depends upon this fact. A virulent organism may also be attenuated by being exposed to an elevated temperature which is insufficient to kill it, as was found by Toussaint in the case of anthrax.

(4) Still another method may be mentioned, namely, the attenuation of the virulence by growing the organism in the presence of weak antiseptics. Chamberland and Roux, for example, succeeded in attenuating the anthrax bacillus by growing it in a medium containing carbolic acid in the proportion of 1 . 600.

These examples will serve to show the principles underlying attenuation of the virulence of an organism. There are, however, still other methods, most of which consist in growing the organism in conditions somewhat unfavourable to its growth, *e.g.*, under compressed air, etc.

(*b*) *Immunity by living Virulent Cultures in Non-lethal Doses.*—Immunity may also be produced by employing virulent

cultures in small, that is non-lethal, doses. In subsequent inoculations the doses may be increased in amount. For example, immunity may thus be obtained in rabbits against the bacillus pyocyaneus. Such a method, however, is difficult to carry out, and it has been found more convenient to commence the process of immunisation with dead or attenuated cultures, and then to continue with virulent cultures.

Exaltation of the Virulence.—The converse process to attenuation, *i.e.*, the exaltation of the virulence, is obtained chiefly by the method of cultivating the organism from animal to animal—the method of *passage* discovered by Pasteur (first, we believe, in the case of an organism obtained from the saliva in hydrophobia, though having no causal relationship to that disease). This is most conveniently done by intraperitoneal injections, as there is less risk of contamination. The organisms in the peritoneal fluid may be used for the subsequent injection, or a culture may be made between each inoculation. The virulence of a great number of organisms can be increased in this way, the animals most frequently used being rabbits and guinea-pigs. This method can be applied to the organisms of typhoid, cholera, pneumonia, to streptococci and staphylococci, and in fact to those organisms generally which invade tissues.

2. **Immunity by Dead Cultures of Bacteria.**—In some cases a high degree of immunity against infection by a given microbe may be developed by repeated and gradually increasing doses of the dead cultures, the cultures being killed sometimes by heat, sometimes by exposure to the vapour of chloroform. In this method the so-called endotoxins will be injected along with the other substances in the bacterial protoplasm, but the resulting immunity is chiefly directed against the vital activity of the organisms—is antibacterial rather than antitoxic (*vide infra*). The cultures when dead produce, of course, less effect than when living, and this method may be conveniently used in the initial stages of active immunisation,—to be afterwards followed by injections of the living cultures. The method is extensively used for experimental purposes, and is that adopted in anti-plague and anti-typhoid inoculations, and in the *treatment* of infections by means of vaccines.

Combination of Methods.—The above methods may be combined in various ways. By repeated injections of cultures at first in the dead condition, then living and attenuated and afterwards more virulent, and by increasing the doses, a high degree of immunity may be obtained.

3. **Immunity by Sensitised Dead Cultures.**—In this method,

which was originally introduced by Besredka, the bacterial emulsion is treated with the corresponding anti-serum, that is, the serum of an animal immunised against the particular bacterium, and after being left in contact for some time, the serum is separated by the centrifuge and the bacteria are thoroughly washed free of all traces of serum. The bacteria thus treated constitute the *vaccins sensibilisés*. It is claimed that, while immunity produced by them is rapidly developed and is of long duration, the local toxic effects on subcutaneous injection are very much lessened. The method has been applied in vaccination against typhoid, plague, cholera, and dysentery. Apparently in such sensitised vaccines the antigen molecules of the bacteria will be largely combined with anti-substances, and thus on theoretical grounds we would expect that only those molecules left free, or those which become free by dissociation, will be able to act as antigens and the antigenic power of the bacteria will be diminished. Certain observations show that this is the case, but it would be desirable to have fuller knowledge of the amounts of anti-substances developed by the sensitised and non-sensitised bacteria respectively and of the relation of such amounts to the degree of protection afforded.

4. **Immunity by the Separated Bacterial Products or Toxins.**—The organisms in a virulent condition are grown in a fluid medium for a certain time, and the fluid is then filtered through a Chamberland or other porcelain filter. The filtrate contains the toxins, and it may be used unaltered, or may be reduced in bulk by evaporation, or may be evaporated to dryness. The process of immunisation by the toxin is started by small non-lethal doses of the strong toxin, or by larger doses of toxin the power of which has been weakened by various methods (*vide infra*). Afterwards the doses are gradually increased. This method was carried out with a great degree of success in the case of diphtheria and tetanus. It appears capable of general application in the case of organisms where it is possible to get an active toxin from the filtered cultures. It has also been applied in the case of snake venoms by Calmette and by Fraser, and a high degree of immunity has been produced.

The following may be mentioned as some of the most important examples of the practical application of the principles of active immunity, *i.e.*, of protective inoculation: (1) Inoculation of sheep and oxen against anthrax (Pasteur) (p. 347); (2) Jennerian vaccination against smallpox (p. 609); (3) Anti-cholera inoculation (Haffkine) (p. 473); (4) Anti-plague inoculation (Haffkine) (p. 498); (5) Anti-typhoid inoculation

(Wright and Semple) (p. 375); (6) Pasteur's method of inoculation against hydrophobia, which involves essentially the same principles (p. 618).

Vaccines as a Method of Treatment.—Within recent years the principles of active immunity have been directly applied in the treatment of already existing disease. This is largely due to the work of Wright, who, from his study of the part played by phagocytosis in the successful combat of bacteria by the tissues, was led to advocate the treatment of bacterial infections by carrying on an active immunisation against the causal agents by the injection of dead cultures of the latter. The justification for such a procedure lies in his contention that in many cases infections are to be looked on as practically localised, *e.g.*, the cases of an acne pustule, or a boil. The view is that while the local capacities of resistance may have been lowered, resisting mechanisms in other parts of the body have not been brought into play. The vaccine may thus stimulate these, and the focus of bacterial growth may be flooded with antibacterial bodies. (With regard to the details of the preparation of the vaccines, see p. 130; the general principles supposed to underlie their use have been discussed in connection with tuberculosis, p. 296.) Vaccines have been used extensively in the treatment of acne, boils, sycosis, tuberculosis, infections of the genito-urinary tract by the b. coli, infections of joints by the gonococcus, and in many cases considerable success has followed the treatment. Favourable results have also been recorded in the case of more general infections, such as ulcerative endocarditis, septicæmia, typhoid fever, etc. In such cases it is stated that the best results are obtained from the use of sensitised vaccines (*vide supra*). These are prepared by subjecting living cultures (preferably of autogenous strains) to the action of say 5 c.c. of the appropriate anti-serum for three hours at 37° C. The sensitised bacteria are deposited by centrifuging, emulsified in saline containing ·5 per cent. phenol, and again kept at 37° C. for three hours, so that the phenol may kill them. The vaccine is then ready for use. In infections with streptococci or the b. coli from ten to forty millions may be given, the dose being repeated in twenty-four hours. In very acute infections a few hundred thousand sensitised bacteria may produce definite results, and if improvement of symptoms occurs the dose may be cautiously repeated in six hours.

Active Immunity by Feeding.—Ehrlich found that mice could be gradually immunised against ricin and abrin by feeding them with increasing quantities of these substances (*vide* p. 193).

In the course of some weeks' treatment in this way the resulting immunity was of so high a degree that the animals could tolerate on subcutaneous inoculation 400 times the dose originally fatal. Fraser also found in the case of snake venom that rabbits could, by being fed with the poison, be immunised against several times the lethal dose of venom injected into the tissues. In such cases some of the molecules which act as antigens apparently pass through the intestinal wall unchanged.

By feeding animals with dead cultures of bacteria or with their separated toxins, a degree of immunity may in some cases be gradually developed. But this method is so much less certain in results, and so much more tedious than the others, that it has obtained no practical applications.

Active immunity of high degree developed by the methods described may be regarded as *specific*, in the sense explained below. A certain degree of immunity, or rather of increased general resistance of parts of the body (for example, the peritoneum), can, however, be produced by the injection of various substances—bouillon, blood serum, solution of nuclein, etc. (Issaeff). These agents probably act by producing a local leucocytosis.

The Properties of the Sera of Highly Immunised Animals.

Anti-substances and their Specificity.—The fundamental fact in passive immunity, namely, that immunity can be transferred to another animal, shows that the serum in question differs from the serum of a normal animal in containing antagonistic substances to the toxin or bacterium as the case may be,—these being generally spoken of as anti-substances. The development of these bodies, first observed in the case of the injection of toxins, is found to occur when a great many different substances are introduced into the tissues of the living body. We can, in fact, divide organic molecules into two classes—those which give rise to the production of anti-substances, and are thus known as *antigens*, and those which have not this property. Amongst the former are various toxins, ferments, molecules of tissue cells, bacteria, red corpuscles, etc. They are all probably of proteid nature, though their true constitution is not known, and none of them have been obtained in a pure condition. Amongst the latter may be placed the various poisons of known constitution, glucosides, alkaloids, etc. We may also state at present that the anti-substance forms a chemical or physical union with the

particular antigen which has led to its development, and we shall discuss the evidence for this later. Furthermore, the anti-substance has apparently a specific combining group which fits, as it were, a group in the corresponding antigen, the two groups having been compared to a lock and key. It is, however, to be noted that this specificity is a chemical or physical one rather than a biological one. An anti-serum, for example, developed by the injection of bacterium A may also have some effect on bacterium B, and thus appear not to be specific. It is known, however, that the antigens in bacterium A are not all identical, and that some of them may be present though in smaller proportion in bacterium B; thus the theory of combining specificity is not invalidated. The number of different anti-substances, as judged by their combining properties, would appear to be almost unlimited, a fact which throws new light on the complexity of the structure of living matter. When anti-substances are studied as regards their action *in vivo* or *in vitro* on the substances with which they combine, different degrees of complexity may be recognised. In certain cases simple combination may occur (antitoxins, antiferments), in other cases physical effects may be associated with combination (agglutinins), and in a third group of cases the anti-body may lead to the union of another body normally present in serum, called complement or alexin. The combination may or may not result in physical changes in the antigen, the evidence of the latter occurrence being elicited by the deviation method (p. 127). Anti-bodies of the third class are known as immune-bodies or amboceptors (Ehrlich) or sensitising substances,—*substances sensibilisatrices* of French writers.

After this preliminary statement in explanation, we shall consider the actual properties of the two classes of serum, and later we shall resume the theoretical consideration.

Antitoxic Serum.—In a previous chapter (p. 186) a distinction has been drawn between exo- and endotoxins, and with regard to these the general statement may be made that while antitoxins are, as a rule, comparatively easily obtained in the case of the former, the matter is quite otherwise in the case of the latter. In fact some writers have gone so far as to say that antitoxins to endotoxins cannot be obtained. Such an extreme view is in our opinion unjustifiable in the light of the recent work on antitoxins to the typhoid, cholera, and dysentery endotoxins (pp. 368, 470, 386). Nevertheless we have the important fact that in many cases by the injection of dead cultures an active anti-bacterial serum can be obtained which has no neutralising action on the endotoxins, and we must conclude

either that a large proportion of the endotoxin does not lead to the production of antitoxin or does so only with great slowness, the latter alternative being on general grounds rather improbable. The best examples of antitoxic sera are those of diphtheria and tetanus, though similar principles and methods are involved in the case of the anti-sera to ricin and abrin, and to snake poison. We shall here speak of diphtheria and tetanus. The steps in the process of preparation may be said to be the following: First, the preparation of a powerful toxin; second, the estimation of the power of the toxin; third, the development of antitoxin in the blood of a suitable animal, by gradually increasing doses of the toxin; fourth, the estimation from time to time of the antitoxic power of the serum of the animal thus treated.

1. *Preparation of the Toxin.*—The mode of preparation and the conditions affecting the development of diphtheria toxin have already been described (p. 408). In the case of tetanus the growth takes place in glucose bouillon under an atmosphere of hydrogen (*vide* p. 429). In either case the culture is filtered through a Chamberland filter when the maximum degree of toxicity has been reached. The term "toxin" is usually applied for convenience to the filtered (*i.e.*, bacterium-free) culture.

2. *Estimation of the Toxin.*—The power of the toxin is estimated by the subcutaneous injection of varying amounts in a number of guinea-pigs, and the minimum dose which will produce death is thus obtained. This, of course, varies in proportion to the weight of the animal, and is expressed accordingly. In the case of diphtheria, in Ehrlich's standard, the minimum lethal dose—known as M.L.D.—is the smallest amount which will certainly cause death in a guinea-pig of 250 grms. within four days. The testing of a toxin directly is a tedious process, and in actual practice, where many toxins have to be dealt with, it is found more convenient to test them by finding how much will be neutralised by a certain amount of a standard antitoxic serum, namely, an "immunity unit" (p. 563).

3. *Development of Antitoxin.*—The earlier experiments on tetanus and diphtheria were performed on small animals, such as guinea-pigs, but afterwards the sheep and the goat were used, and finally horses. In the case of the small animals it was found advisable to use in the first stages of the process either a weak toxin or a powerful toxin modified by certain methods. Such methods are the addition to the toxin of terchloride of iodine (Behring and Kitasato), the addition of Gram's iodine solution in the proportion of one to three (Roux and Vaillard), and the plan, adopted by Vaillard in the case of tetanus, of

using a series of toxins weakened to varying degrees by being exposed to different temperatures, namely, 60°, and 55°, and 50° C. In the case of large animals immunisation is sometimes started with small doses of unaltered toxin; and the doses are gradually increased. The toxin is at first injected into the subcutaneous tissues, later into a vein. Ultimately 300 c.c., or more, of active diphtheria toxin thus injected may be borne by a horse, such a degree of resistance being developed after the treatment has been carried out for two or three months. The antitoxin content of the serum is estimated from time to time, the object being, of course, to raise it to as high a figure as possible. It is found that each injection produces a certain amount of fall in the antitoxin value, and this, in favourable cases, is followed by a rise to a higher level than before, the former event being due in part to the combination of a portion of the antitoxin with the toxin introduced. (Similar phenomena are observed in the development of all other classes of anti-substances.) In all cases of immunising the general health of the animal ought not to suffer. If the process is pushed too rapidly the antitoxic power of the serum may diminish instead of increasing, and a condition of marasmus may set in and may even lead to the death of the animal. After a sufficiently high degree of antitoxic power has been reached, the animal is bled under aseptic precautions, and the serum is allowed to separate in the usual manner. It is then ready for use, but some weak antiseptic, such as ·5 per cent. carbolic acid, is usually added to prevent its decomposing. Other antitoxic sera are prepared in a corresponding manner. Some further facts about antitetanic serum are given on p. 433. (In immunisation of small animals an indication of their general condition may be obtained by weighing them from time to time.)

4. *Estimating the Antitoxic Power of, or "Standardising," the Serum.*—This is done by testing the effect of various quantities of the serum of the immunised animal against a certain amount of toxin. Various standards have been used, of which the two chief are that of Ehrlich and that of Roux. Ehrlich adopted as the *immunity unit* the amount of antitoxic serum which will neutralise 100 times the minimum lethal dose of toxin, serum and toxin being mixed together, diluted up to 4 c.c. and injected subcutaneously into a guinea-pig of 250 grms. weight, the prevention of the death of the animal within four days being taken as the indication of neutralisation. 1 c.c. of a serum, of which ·02 c.c. will protect against a hundred times the lethal dose, will possess 50 immunity units, and 20 c.c. of this serum

1000 immunity units. Sera have been prepared of which 1 c.c. has the value of 800 units or even more. As a standard in testing, Ehrlich employs quantities of serum of known antitoxic power in a dry condition, preserved in a vacuum in a cool place, and in the absence of light. A thoroughly dry condition is ensured by having the glass bulb containing the dried serum connected with another bulb containing anhydrous phosphoric acid. With such a standard test-serum any newly prepared serum can readily be compared.

Roux has adopted a standard which represents the animal weight in grammes protected by 1 c.c. of serum against the dose of virulent bacilli lethal to a control guinea-pig in thirty hours, the serum being injected twelve hours previously. Thus, if ·01 c.c. of a serum will protect a guinea-pig of 500 grms. against the lethal dose, 1 c.c. (1 grm.) will protect 50,000 grms. of guinea-pig, and the value of the serum will be 50,000.

Sera of Animals immunised against Vegetable and Animal Poisons.—It was found by Ehrlich in the case of the vegetable toxins, ricin and abrin, and also by Calmette and Fraser in the case of the snake poisons, that the serum of animals immunised against these respective substances had a protective effect when injected along with them into other animals. Ehrlich found, for example, that the serum of a mouse which had been highly immunised against ricin by feeding as described above, could protect another mouse against forty times the fatal dose of that substance. He considered that in the case of the two poisons, antagonistic substances —"anti-ricin" and "anti-abrin"—were developed in the blood of the highly immunised animals. A corresponding antagonistic body, to which Fraser gave the name "antivenin," appears in the blood of animals in the process of immunisation against snake poison.

These investigations are specially instructive, as such vegetable and animal poisons, both as regards their local action and the general toxic phenomena produced by them, present, as we have seen, an analogy to various toxins of bacteria.

Nature of Antitoxic Action.—This subject is only part of the general question with regard to the relation of anti-substances to their corresponding antigens, but it is with regard to antitoxic action that most of the work has been done. We have to consider here two points, namely, (*a*) the relation of antitoxin to toxin, and (*b*) the source of the antitoxin. With regard to the former subject there is now no doubt that the antagonism between toxin and antitoxin is not a physiological one, but that the two bodies unite *in vitro* to form a compound inert towards the living tissues, there being in the toxin molecule an atom group which has a specific affinity for the antitoxin molecule or part of it.

When toxin and antitoxin are brought together *in vitro*, it can be proved that their behaviour towards each other resembles what is observed in chemical union. Thus it has been found

that a definite period of time elapses before the neutralisation of the toxin is complete, that neutralisation takes place more rapidly in strong solutions than in weak, and that it is hastened by warmth and delayed by cold. C. J. Martin and Cherry, and also Brodie, showed that in the case of diphtheria toxin and in that of an Australian snake poison, the toxin molecules will pass through a colloid membrane (p. 191), whilst those of the corresponding antitoxin will not. Now, if a mixture of equivalent parts of toxin and antitoxin is freshly prepared and at once filtered, a certain amount of toxin will pass through, but the longer such a mixture is allowed to stand before filtration the less toxin passes, till a time is reached when no toxin is found in the filtrate. Further, if the portion of fluid which at this stage has not passed through the filter be injected into an animal no symptoms take place; this shows that after a time neutralisation is complete. Again, in cases where the toxin has some definite physical effect, demonstrable *in vitro*, *e.g.*, lysis, agglutination, coagulation, or the prevention of coagulation, its action can be annulled by the antitoxin; in such circumstances manifestly no physiological action of antitoxin through the medium of the cells of the body can come into play. These facts are practically conclusive in favour of antitoxin action depending upon a direct union of the two substances concerned, and Morgenroth has shown that the combination toxin-antitoxin can be broken up by the action of hydrochloric acid and the two constituents recovered.

Although authorities are now agreed as to the direct combination of toxin and antitoxin, there is still much uncertainty as to the exact nature of this union. Regarding this subject there may be said to be three chief views—(*a*) that of Ehrlich, according to which there is a firm chemical union of toxin and antitoxin, and the former is not homogeneous but has a complex structure; (*b*) that of Arrhenius and Madsen, who consider that the phenomena correspond to the behaviour of two substances in weak chemical union; and (*c*) that of Bordet, who regards the combination to be not of chemical, but of physical nature, corresponding to a process of adsorption. Controversy on this question may be said to date from the important work of Ehrlich on the neutralisation of diphtheria toxin. Using an immunity unit of antitoxin (the equivalent of 100 doses of toxin) he determined with any example of crude toxin the largest amount of toxin which could be neutralised completely, so that no symptoms resulted from an injection of the mixture. This amount he called the *limes null* dose, expressed as L_o. He then investigated the effects of adding further amounts of toxin to the immunity unit and observed the quantity which was first sufficient to produce a fatal result, that is, which contained one M.L.D. of free toxin; this amount he called the *limes tödtlich*, fatal limit, expressed as L_t. Now if, as he supposed, the union of toxin and antitoxin resembled that of a strong acid and

base, $L_t - L_o$ ought to be the equivalent of a minimum lethal dose of the toxin alone. This, however, was never found to be the case, the difference being always considerably more than one M.L.D. For example, in the case of one toxin, M.L.D. = ·0165 c.c., L_t = 1·26 c.c., L_o = ·9 c.c.; difference = ·36 c.c., *i.e.*, 21·9 M.L.D. This, in brief, is what is known as the "Ehrlich phenomenon," and it has been explained by him as the result of the presence of toxoids (*vide* p. 195), *i.e.*, toxin molecules in which the toxophorous group has become degenerated. He distinguishes three possible varieties of such bodies according to the affinity of the haptophorous group, namely, *prototoxoid* with more powerful affinity than the toxin molecule, *epitoxoid* with less powerful affinity, and *syntoxoid* with equal affinity. The presence of epitoxoids would manifestly explain the above phenomenon. The L_o dose would represent toxin + epitoxoid molecules all united to antitoxin molecules, and the addition of another M.L.D. of toxin would not result in there being a free fatal dose, but in the added toxin taking the place of epitoxoid. Several lethal doses would need to be added before the mixture was sufficient to produce a fatal result—that is, $L_t - L_o$ would equal several M.L.D.'s.

Ehrlich observed another fact strongly in favour of the existence of toxoids, namely, that in the course of time the toxin might become much weakened, so that in one case observed the M.L.D. came to be three times the original fatal dose, and still the amount of antitoxin necessary to neutralise it completely was the same as before. Ehrlich also investigated the effects of partial neutralisation of the L_o amount of toxin—that is, he added to this amount different fractions of an immunity unit and estimated the toxicity of the mixture. He found by this method that the neutralisation of the toxin did not take place gradually, but as if there were distinct bodies present with different combining affinities—the graphic representation of the effects of the mixture not being a curve but a step-stair line. Thus he distinguished proto-, deutero-, and trito-toxins (with corresponding toxoids). It will thus be seen that Ehrlich regarded the combination toxin-antitoxin to be a firm one, and that the neutralisation phenomena are to be explained by the complicated constitution of the crude toxin.

The chief criticism of Ehrlich's views has come from the important work of Madsen and Arrhenius. Their main contention is that the toxin-antitoxin combination is not a firm one but a reversible one, and is governed by the laws of physical chemistry. For example, in the case of a mixture of ammonia and boracic acid (*i.e.*, of a weak base and a weak acid) in solution, there is a constant relation between the amounts of each of the substances in the free condition and the amounts in combination, —the combination is reversible, so that if some of the free ammonia were removed a certain amount of the combined ammonia would become dissociated to take its place; further, if to the mixture, in a state of equilibrium, more ammonia or more boracic acid were added, part would remain free while part would combine. Accordingly, if toxin and antitoxin behaved in a similar manner, an explanation of the Ehrlich phenomenon would be afforded. Madsen and Arrhenius have worked out the question in the case of a great many toxins, and find that the graphic representation of neutralisation is in every case a curve which can be represented by a formula.

It should be noted in connection with this controversy that there are two questions which may be independent of each other,

namely: (1) Does the "toxin" in any particular case represent a single substance or several? (2) What is the nature of the combination of any one constituent substance and its anti-substance—is it reversible or is it not? It seems impossible to explain the facts with regard to diphtheria toxin on the hypothesis of a single substance, even if this should have its combining and toxic actions equally weakened; "toxoids" in Ehrlich's sense must in our opinion be supposed. Then there is an important fact established by Danysz and by v. Dungern, namely, that the amount of toxin neutralisable by a given amount of antitoxin is different according as the toxin is added in several moieties or all at once—in the latter case the amount of toxin neutralisable is greater. There seems no explanation of this according to the view of Madsen and Arrhenius, as the same state of equilibrium ought to be reached in the two cases—that is, the amounts of toxin neutralised should be the same.

An important factor in the union of toxin and antitoxin is the time necessary for the union to be complete. Morgenroth has shown that in the case of diphtheria toxin this is considerable, —about twenty-four hours. Up to this time, mixtures of toxin and antitoxin, when injected intravenously, show decreasing degrees of toxicity according to the time they have been kept. On the other hand, when the subcutaneous method of injection is used the time interval has no effect, and this he considers to be due to a catalytic action of the tissues which accelerates the union of the two substances. A striking phenomenon, which apparently points to the reversibility of the combination, was noted by Behring in the case of diphtheria toxin, and afterwards studied by Madsen and by Otto and Sachs in the case of botulismus toxin, namely, that when a certain amount of a mixture of toxin and antitoxin was found to be neutral on injection, a fraction of this amount might produce toxic phenomena or even death. This was apparently due to dissociation of the toxin in the greater dilution, and in favour of this being the case Otto and Sachs found that when the mixture was allowed to stand for twenty-four hours, so that combination was complete, the phenomenon no longer occurred. Other facts might be brought forward which show that the firmness of union of toxin and antitoxin increases with time, or in other words, that dissociation becomes more difficult. It was shown by Morgenroth, and by Muir independently, that the union of a hæmolytic immune-body with the corresponding red corpuscle was of reversible nature, and the latter observer found that in this case the union was not increased in firmness after twenty-four hours.

There is little doubt that there are varying degrees of firmness of union of an antigen and its anti-substance, and varying periods necessary for the combination to become complete.

There has recently been a tendency on the part of some authorities to consider that the union of toxin-antitoxin does not correspond to what takes place in ordinary chemical union, but is a physical interaction of bodies in a colloidal state, the action being one of the so-called adsorption phenomena. The smaller toxin molecule becomes entangled, as it were, in the larger antitoxin one, very much as a dye becomes attached to the structure of a thread. Bordet has long maintained a theory of this nature, and gives reasons for believing that there is no definite quantitative relationship in the combination of the molecules of the two substances, different amounts of antitoxin affecting in varying degree all the molecules of a given amount of toxin. A statement on the general question is at present impossible; we can only say that *direct combination of the two bodies does occur; that sometimes, probably often, the "toxin" contains different toxic bodies with varying affinity; and that in a few instances the combination has been proved to be reversible, but to what extent this is generally true remains still to be determined. In all cases the outstanding feature is the specific nature of the combination, and of this no satisfactory explanation can as yet be given.*

The next question to be considered is the *source* of antitoxin. The following three possibilities present themselves: (*a*) antitoxin may be formed from the toxin, *i.e.*, may be a "modified toxin"; (*b*) antitoxin may be the result of an increased formation of molecules normally present in the tissues; (*c*) antitoxin may be an entirely new product of the cells of the body. It can now be stated that antitoxin is not a modified toxin. It has been shown, for example, that the amount of antitoxin produced by an animal may be many times greater than the equivalent of toxin injected; and further, that when an animal is bled the total amount of antitoxin in the blood may some time afterwards be greater than it was immediately after the bleeding, even although no additional toxin is introduced. This latter circumstance shows that antitoxin is *formed* by the cells of the body. If antitoxin is a product of the cells of the body, we are almost compelled, on theoretical grounds, to conclude that it is not a newly manufactured substance, but a normal constituent of the living cells which is produced in increased quantity. We have, however, direct evidence of the presence of antitoxin under normal conditions,—the presence of such being shown by its uniting with

toxin and rendering it inert. Normal horse serum, to mention an example, may have a varying amount of antitoxic action to the diphtheria poison, ox-bile has a similar action to snake poison, whilst in the case of other anti-substances—such as agglutinins, bacteriolysins, hæmolysins, etc.—whose production is governed by the same laws, numerous examples might be given. It is, however, rather to the protoplasm of living cells than to the serum that we must look for the source of antitoxins. In the first place, we have evidence that in the living body bacterial toxins enter into combination with, or, as it is often expressed, are fixed by the tissues—presumably by means of certain combining affinities. This has been shown by the experiments of Dönitz and of Heymans with tetanus toxin. We have, in such cases, however, no evidence as to where the toxin is fixed beyond that supplied by the occurrence of symptoms. Another line of research which has been followed is to bring emulsions of various organs into contact with a given toxin and observe whether any of the toxicity is removed. This was first carried out by Wassermann and Takaki, who investigated the action of emulsions of the central nervous system of the susceptible guinea-pig on tetanus toxin. They found in this way that the nervous system contained bodies which had a neutralising effect on the toxin. For example, it was shown that 1 c.c. of emulsion of brain and spinal cord was capable of protecting a mouse against ten times the fatal dose of toxin. These observations have been confirmed, though their significance has been variously interpreted: and in view of the ascertained facts with regard to processes of physical adsorption, it is quite possible that this neutralisation of toxin does not represent a specific union as in the case of antitoxin action. We may note, however, that it is not a serious objection, that in certain animals other tissues than that of the central nervous system can combine with tetanus toxin—this might take place with or without resulting symptoms.

It will be seen from what has been stated with regard to the relation of toxin and antitoxin, that the fixation of toxin by the tissues leads up theoretically to the possible production of antitoxin. In other words, the substance which, when forming part of the cells, fixes the toxin and thus serves as the means of poisoning, may act as an antitoxin when free in the blood. This will be discussed below in connection with Ehrlich's theory of passive immunity. We may conclude by saying *that antitoxin is probably represented by molecules normally present in the cells or* (*more rarely*) *in the fluids of the body.*

Of the *chemical nature of antitoxins* we know little. From

their experiments C. J. Martin and Cherry deduced that while toxins are probably of the nature of albumoses, the antitoxins probably have a molecule of greater size, and may be allied to the globulins. Such a supposed difference in the sizes of the molecules might explain the fact, observed by Fraser and also by C. J. Martin, that antitoxin is much more slowly absorbed when introduced subcutaneously than is the case with toxin. Hiss and Atkinson also came to the conclusion that antitoxin belongs to the globulins. They found that the precipitate with magnesium sulphate from anti-diphtheria serum contained practically all the antitoxins, and that any substance obtained which had an antitoxic value gave all the reactions of a globulin; and this result has been confirmed by others. They also found that the percentage amount of globulin precipitated from the serum of the horse increased after it was treated in the usual way for the production of antitoxin. Ledingham observed an increase of globulin during the process of immunisation of a horse which yielded a high-grade antitoxic serum, and he ascertained that while this increase was more on the part of the euglobulin than of the pseudoglobulin fraction, most of the antitoxin was contained in the latter.

Antitoxin, when present in the serum, leaves the body by the various secretions, and in these it has been found, though in much less concentration than in the blood. It is present in the milk, and a certain degree of immunity can be conferred on animals by feeding them with such milk, as has been shown by Ehrlich, Klemperer, and others. Klemperer also found traces of antitoxin in the yolk of eggs of hens whose serum contained antitoxin. Bulloch also found in the case of hæmolytic sera (*vide infra*) that the anti-substance ("immune-body") is transmitted from the mother to the offspring.

Antibacterial Serum.—The stages in the preparation of antibacterial sera correspond to those in the case of antitoxic sera, but living, or, in the early stages, dead cultures are used instead of toxin separated by filtration, and in order to obtain a serum of high antibacterial power it may ultimately be necessary to use a very virulent culture in large doses. For this purpose a fairly virulent culture is obtained fresh from a case of the particular disease, and its virulence may be further increased by the method of *passage*. This method of obtaining a high degree of immunity against the microbe is specially applicable in the case of those organisms which invade the tissues and multiply to a great extent within the body, and of which the toxic effects, though always existent, are proportionately small

in relation to the number of organisms present. The method has been applied in the case of the typhoid and cholera organisms, the bacillus of bubonic plague, the bacillus coli communis, the pneumococcus, streptococcus (Marmorek), and many others. In fact, it seems capable of very general application.

The important result obtained by such experiments is, that if an animal be highly immunised by the method mentioned, the development of the immunity is accompanied by the appearance in the blood of *protective* substances, which can be transferred to another animal. The law enunciated by Behring regarding immunity against toxins thus holds good in the case of the living organisms, as was first shown by Pfeiffer. The latter found, for example, that in the case of the cholera organisms, so high a degree of immunity could be produced in the guinea-pig, that ·002 c.c. of its serum would protect another guinea-pig against ten times the lethal dose of the organisms, when injected along with them. Here again is presented the remarkable potency of the antagonising substances in the serum, which in this case lead to the destruction of the corresponding microbe.

The *anti-streptococcic serum* of Marmorek may be briefly described, as it has come into extensive practical use. This observer found that he could intensify the virulence of a streptococcus by growing it alternately in the peritoneal cavity of a guinea-pig and in a mixture of human blood serum and bouillon (*vide* p. 42). The virulence became so enormously increased by this method, that when only one or two organisms were introduced into the tissues of a rabbit a rapidly fatal septicæmia was produced. Streptococci of this high degree of virulence were used first by subcutaneous, afterwards by intravenous injection, to develop a high degree of resistance in the horse. Injections were continued over a considerable period of time, and the protective power of the serum was tested by mixing it with a certain dose of the virulent organisms, and then injecting into a rabbit. The serum of a horse highly immunised in this way constitutes the anti-streptococcic serum which has been extensively used in many cases of streptococcic invasion in the human subject. Marmorek, however, found that this serum had little antitoxic power—that is, could only protect from a comparatively small dose of toxin obtained by filtration of cultures.

Anti-typhoid, anti-cholera,[1] anti-pneumococcic, anti-meningococcic, anti-plague, and other sera are all prepared in an analogous manner.

Properties of Antibacterial Serum.—We have here to consider the three main actions mentioned above, namely, (*a*) bactericidal and lysogenic action, (*b*) opsonic action, and (*c*) agglutinative and the closely allied precipitating action. Of

[1] A true *antitoxic* cholera serum was prepared by Metchnikoff, E. Roux, and Taurelli-Salimbeni.

these the two first are concerned with the protective property of an antibacterial serum.

(*a*) *Bactericidal and Lysogenic Action.*—Pfeiffer found that if certain organisms, *e.g.*, the cholera spirillum, were injected into the peritoneal cavity of a guinea-pig highly immunised against these organisms, they lost their motility almost immediately, gradually became granular, swollen, and then disappeared in the fluid—these changes constitute what is now generally known as "Pfeiffer's phenomenon" or bacteriolysis. It was subsequently shown, however, by Metchnikoff and by Bordet that bacteriolysis might occur outside the body by the addition of fresh peritoneal fluid or normal serum to the heated immune-serum. Pfeiffer also found that an anti-serum heated to 70° C. for an hour produced the reaction when injected with the corresponding organisms into the peritoneum of a fresh animal. The outcome of these and subsequent researches is to show that when an animal is immunised against a bacterium, there appears in its serum an anti-substance, which is generally known as *immune-body*, *amboceptor* (Ehrlich), or *substance sensibilisatrice* (Bordet), is comparatively stable, resisting usually a temperature of 70° C., for an hour. It cannot produce the destructive effect alone, but requires the addition of a substance normally present in the serum, which is spoken of under various names—*complément* (Ehrlich), *alexin* or *cytase* (French writers). The complement is relatively unstable, being rapidly destroyed by a temperature of 60° C., and it is not increased in amount during the process of immunisation. Though ferment-like in its instability, it differs from a ferment in being fixed or used up in definite quantities.

Observation has shown that complement is not a single substance, but is really made up of two components. Ferrata, who was the first to establish this fact, employed the following method: Fresh guinea-pig's serum is dialysed against running water for twenty-four hours; the precipitate which has formed at the end of that time is separated by the centrifuge, washed several times in distilled water, and then dissolved in normal salt solution. The separated fluid is passed through thick filter paper. The component in the solution of the precipitate unites directly with sensitised corpuscles—and then that in the separated fluid enters into combination; hence they have been called by Brand "middle-piece" and "end-piece" respectively. The separation by such a method is, however, far from being a complete one. The method of Liefmann, which is the most satisfactory, is the following: The serum is diluted by the addition of nine volumes of distilled water, and then carbonic acid gas is passed through till the globulin is precipitated. The precipitate is separated off by the centrifuge, and the clear fluid contains the end-piece, diluted, of course, ten times: The precipitate, containing the mid-piece, is dissolved in ·8 per cent. sodium chloride solution, a con-

venient amount being twice the volume of the original serum. During the process of preparation, and afterwards, the serum and the diluting fluids ought to be chilled to a temperature a little above 0° C.; the serum should also be used as fresh as possible after the blood is withdrawn from the body.

The phenomenon of bacteriolysis is, however, only seen in the case of certain organisms when an animal is highly immunised against them; the typhoid and cholera group are outstanding examples. It is also to be noted that it sometimes is seen in the case of a normal serum (*vide* Natural Immunity). In other cases the bactericidal effect of a serum may occur without the rapid dissolution characteristic of lysogenesis, though other structural changes may be produced. In still other instances, *e.g.*, the anti-sera to staphylococci, streptococci, plague bacilli, etc., a bactericidal effect may be wanting; nevertheless it may be shown that an immune-body is developed in the process of immunisation. This may be done by observing the increased amount of complement which is fixed through the medium of the anti-serum (immune-body), sensitised red corpuscles being used as the test for the presence of free complement. The method is described on p. 127.

The all-important action of the immune-body is thus to bring an increased amount of complement into union with bacteria; whether death of the bacteria will result or not will depend ultimately on their sensitiveness to the action of the particular complement.

It is to be noted that in the case of a bactericidal serum there is an optimum amount of immune-body which gives the greatest bactericidal effect with a given amount of complement. If this amount of immune-body be exceeded, the bactericidal action becomes diminished and may be practically annulled. This result, which is generally known as the "Neisser-Wechsberg phenomenon," has been the subject of much controversy, and cannot yet be said to be satisfactorily explained. It would accordingly be out of place to discuss here the different views with regard to it. (Regarding some theoretical considerations as to the therapeutic applications of antibacterial sera, *vide* p. 584.)

The laws of lysogenesis are, however, not peculiar to the case of solution of bacteria by the fluids of the body, but hold also in the case of other organised substances, red corpuscles, leucocytes, etc., when these are introduced into the tissues of an animal as in a process of immunisation. Of such sera the hæmolytic have been most fully studied, and, owing to the

delicacy of the reaction and the ease with which it can be observed, have been the means of throwing much light on the process of lysogenesis, and thus on one part of the subject of immunity. A short account of their properties may now be given.

Hæmolytic and other Sera.—It has long been known that in some instances the blood serum of one animal has, in a certain degree, the power of dissolving the red corpuscles of another animal of different species; in other instances, however, this property cannot be detected. Bordet showed that if one animal were treated with repeated injections of the corpuscles of another of different species, the serum of the former acquired a marked hæmolytic property towards the corpuscles of the latter, the property being demonstrated when the serum is added to the corpuscles. He also found that the hæmolytic property disappeared when the hæmolytic serum was heated at 55° C., but, as in the case of a bacteriolytic serum, was regained on the subsequent addition of some serum from a fresh (*i.e.*, non-treated) animal. These observations have been fully confirmed and greatly extended. Ehrlich and Morgenroth analysed the phenomena in question, and showed that the specially developed and heat-resisting substance, "immune-body," entered into combination with the red corpuscles at a comparatively low temperature, namely, at 0° C.; whereas complement does not combine at this temperature. In this way a method is supplied by which the immune-body can be removed from a hæmolytic serum while the complement is left. They came to the conclusion that immune-body combined with the complement, though the combination was less firm and only occurred at a higher temperature—best about 37° C. They therefore consider that the immune-body acts as a sort of connecting-link between the red corpuscle and the complement, hence the term "amboceptor" which Ehrlich afterwards applied. It may be stated, however, that the direct union of complement and immune-body has not been conclusively demonstrated. Muir and Browning, for example, found that when a fresh serum is passed through a Berkefeld filter, complement is largely retained in the pores of the filter, whereas immune-body passes through practically unchanged; and that if a mixture of complement and immune-body be made and filtered at a temperature of 37° C., the amount of immune-body which passes through is not diminished, whereas it would be if it had united with the retained complement. Accordingly by this method there was obtained no evidence of the direct union of immune-body and complement.

Bordet holds that the immune-body acts merely as a sensitising agent—hence the term *substance sensibilisatrice*—and allows the ferment-like complement to unite. It is quite evident from his writings, however, that he does not mean, as is often assumed, that the immune-body causes some lesion in the corpuscle which allows the complement to act, but simply that it produces in the molecules (receptors) of the red corpuscles an avidity for complement. All that we can say definitely at present is that the combination of receptor + immune-body takes up complement in firm union while neither does so alone. Even after the corpuscles are laked with water the receptors are not destroyed. Muir and Ferguson have shown that they can still take up immune-body and, through its medium, complement, just as the intact corpuscles do. Ehrlich and Morgenroth showed that in some cases the red corpuscles can take up much more immune-body than is necessary for their lysis, and Muir found in one case studied, that each further dose of immune-body led to the fixation of more complement, so that as many as ten times the hæmolytic dose of complement might thus be used up. It is a matter of considerable importance that the union of immune-body and red corpuscles can be shown to be a reversible action. If, as was found by Morgenroth and Muir independently, corpuscles treated with several doses of immune-body and then repeatedly washed in salt solution be mixed with untreated corpuscles and allowed to remain for an hour, then sufficient immune-body will pass from the former to the latter, so that all become lysed on the addition of sufficient complement. The combination of complement, on the other hand, is usually of very firm nature. It has been a disputed point whether there are several distinct complements in a normal serum with different relations to different immune-bodies, for which Ehrlich and his co-workers have brought forward a certain amount of evidence, or whether, as Bordet holds, there is a single complement which may, however, show slight variations in behaviour towards different immune-bodies. There is at least no doubt that all the complement molecules in a serum are not the same. For example, Muir and Browning have shown that the treatment of a normal serum with a small amount of emulsion of a bacterium will remove the bactericidal action for another bacterium, whereas the amount of complement as tested by hæmolysis is practically unchanged. They accordingly consider that there is a moiety of complement, "bacteriophilic complement," which is specially concerned in bactericidal action. On the other hand, many of the arguments adduced

by Ehrlich and his co-workers in favour of a multiplicity of complements are open to another interpretation; the truth probably lies between Ehrlich's and Bordet's views. Workers of the French school also hold that complement does not exist in the free condition in the blood, but is liberated from the leucocytes when the blood is shed. This cannot be held as proved. On the contrary, there are facts which are strongly in support of the view that complement exists in the free condition in the circulating blood. There is, however, evidence that the amount of free complement increases after the blood is shed and some time later gradually diminishes.

The hæmolytic action of a *normal* serum can be shown in many cases to be of the same nature as that of an immune-serum, that is, complement and the homologue of an immune-body can be distinguished. For example, guinea-pig's serum is hæmolytic to ox's corpuscles; if a portion of serum be heated at 55° C., the complement will be destroyed; if another portion be treated with ox's corpuscles at 0° C., the natural immune-body will be removed and only complement will be left. Neither portion is in itself hæmolytic, but this property becomes manifest again when the two portions are mixed. Hæmolytic sera are of great service in the study of the question of specificity. Each is specific in the sense already explained (p. 561), but the serum developed against the corpuscles of an animal may have some action on those of an allied species, that is, some receptors are common to the two species. This fact can be readily shown by the usual absorption tests, for example, in the case of an anti-ox serum tested on sheep's corpuscles. A close analogy holds to what has been established in the case of agglutinins. It is further of great interest to note that by the injection of red corpuscles into an animal its serum not only becomes hæmolytic, but in many cases when heated at 55° C. possesses also agglutinating and opsonic properties towards the red corpuscles used. These facts show how close an analogy obtains between antibacterial and hæmolytic sera, and how important a bearing hæmolytic studies have on the questions of immunity in general.

In addition to hæmolytic sera, anti-sera have been obtained by the injection of leucocytes, spermatozoa, ciliated epithelium, liver cells, nervous tissue, etc. The laws governing the production and properties of these are identical, that is, each serum exhibits a specific property towards the body used in its production—*i.e.*, dissolves leucocytes, immobilises spermatozoa, etc. The specificity is, however, not so marked as in the case of sera produced against red blood corpuscles; thus a serum produced against tissue cells is often hæmolytic; this is probably due to various cells of the body having the same receptors. Here again, when the anti-serum produces no destructive effect on the corresponding cells, the presence of an immune-body may be demonstrated by the increased amount of complement which is taken up through its medium. It may also be mentioned that each anti-serum usually exhibits toxic properties towards the animal whose cells have been used in the injections, *e.g.*, a hæmolytic serum may produce a fatal result, with signs of extensive blood destruction, hæmoglobinuria, etc., *i.e.*, it is hæmotoxic for the particular animal; a serum prepared by injection of liver cells has been found to produce on injection necrotic changes in the liver in the species of animal

whose liver cells were used. These are mentioned as examples of a very large group of specific activities.

With regard to the sites of origin of immune-bodies our information is still very deficient. Pfeiffer and Marx brought forward evidence in the case of typhoid, and Wassermann in the case of cholera, that the immune-bodies are chiefly formed in the spleen, lymphatic glands, and bone-marrow. According to certain workers of the French school, the chief source of anti-substances acting on cells such as red blood corpuscles is the large mononuclear leucocytes, whilst those acting on bacteria are chiefly derived from the polymorpho-nuclear leucocytes (*vide* p. 589). Another view is that immune-bodies are chiefly formed by the large mononuclear leucocytes, whilst complements are products of the polymorphs. That these cells are concerned in the production of antagonistic and protective substances is almost certain, though another possible source of wide extent, namely, the endothelium of the vascular system, has been largely overlooked. As yet, definite statements cannot be made on this point.

(*b*) *Opsonic Action.*—The presence of a substance in an immune-serum which makes the corresponding organism sensitive to phagocytosis was first demonstrated by Denys and Leclef in 1895, in the case of an anti-streptococcal serum. They also showed that the serum produced this effect by acting on the organism, not on the leucocytes. It is, however, chiefly to the researches of Wright and his co-workers that this subject has come into special prominence. Wright and Douglas in their first paper showed that the phagocytosis of staphylococci by leucocytes depended on a body in the normal serum which became fixed to the cocci and made them a prey to the phagocytes. To this they gave the name of "opsonin" (*vide* p. 120). There is no phagocytosis of cocci by leucocytes washed in salt solution; normal serum heated to 55° C. is also without effect in inducing this phenomenon. They could not demonstrate any effect of the opsonin on the leucocytes. On the other hand, if bacteria be exposed to the fresh serum, and they be freed from the excess of serum and then exposed to leucocytes, also washed free from serum, they will be readily taken up by the cells. It has been shown that the opsonic action of the serum against an organism is increased by the process of immunisation, and the opsonic index represents the degree of immunity in one of its aspects as already explained (p. 122). The matter has, however, become complicated by the fact that in an immune-serum an opsonin may still be present after the

serum is heated at 55° C., as has been shown by G. Dean and others; and Muir and Martin have shown that this thermostable immune-opsonin (bacteriotropin of Neufeld) has all the specific characters of anti-substances in general. On the other hand, they have found that the thermolabile opsonin of a normal serum has quite different properties. For example, when a normal serum is tested on a particular bacterium, the opsonic effect on that bacterium may be removed by treating the serum with other bacteria; in other words, the thermolabile opsonin of normal serum does not possess the specific character of the opsonin developed in the process of immunisation. They have also found that various substances or combinations of substances which act as "complement absorbers" also remove the opsonic property from a normal serum, while they have no effect on an immune-opsonin.

That this thermolabile normal opsonin can act in a non-specific way is shown by the fact that particles of carmine and other substances become opsonised by the action of normal serum. It is, however, to be noted that in certain cases there have been found in a normal serum traces of substances which can be activated by thermolabile opsonin after the manner of immune-body and complement (as seen in the hæmolytic action of a normal serum, p. 576); to this extent the opsonic effect of a normal serum may have some degree of specificity. From this and other facts some observers have attempted to explain the whole of opsonic action according to the scheme of *immune-body + complement* as seen in hæmolysis. This, however, is not justifiable, since normal thermolabile opsonin can, as we have seen, act by itself, as can also the specific immune-opsonin after normal opsonin has been destroyed by heating; and we know of no corresponding action in the case of an immune-body. The subject is one of considerable complexity, but it may be said that the most important variations in the opsonic content observed in infections depend on the specific immune-opsonins, though the presence of immune-body may play a part in raising the index, by leading to the union of more normal-complement-opsonin.

(*c*) *Agglutination.*—Charrin and Roger in 1889 observed that when the bacillus pyocyaneus was grown in the serum of an animal immunised against this organism, the growth formed a deposit at the foot of the vessel; whereas a growth in normal serum produced a uniform turbidity. Grüber and Durham, in investigating Pfeiffer's reaction, found that when a small quantity of an anti-serum is added to an emulsion of the corresponding

bacterium, the organisms become agglutinated into clumps, this phenomenon depending upon the presence of bodies in the serum called *agglutinins*.

It had already been found that the serum of convalescents from typhoid fever could protect animals to a certain extent against typhoid fever, and, in view of the facts experimentally established, it appeared a natural proceeding to inquire whether such serum possessed an agglutinative action and at what stage of the disease it appeared. The result, obtained independently by Grünbaum and Widal, but first published by the latter, was to show that the serum possessed this specific action shortly after infection had taken place; in other words, the development of this variety of anti-substance can be demonstrated at an early stage of the disease. Agglutination may be said to be observed generally in bacterial infections, though the degree of the phenomenon and the facility with which it can be noted vary greatly in different cases. Details will be found in the chapters dealing with individual diseases, etc. Furthermore, the phenomenon is not peculiar to bacteria; it is seen, for example, when an animal is injected with the red corpuscles of another species, *hæmagglutinins* appearing in the serum, which have a corresponding specificity.

The physical changes on which agglutination depends cannot as yet be said to be fully understood. It has been shown by Nicolle and by Kruse that if an old bacterial culture be filtered through porcelain, the addition of some of the corresponding anti-serum produces a sort of granular precipitate in it; and that when minute inorganic particles are added to the mixture, they become aggregated into clumps, as in the agglutination of bacteria. The phenomenon would thus appear to be the result of the interaction of the agglutinin and some substance in the bacterial cell which is known as the agglutinable substance or as the agglutinogen, the resulting effect being allied to precipitation. Joos has found in the case of the typhoid bacillus that there are two agglutinable substances which differ in their resistance to heat—α and β agglutinogen, and that they give rise to corresponding agglutinins. Further, as the result of a comparative study of the agglutinins of a motile and a non-motile variety of the hog cholera bacillus, Theobald Smith has come to the conclusion that there is an agglutinin which is produced by and acts on the flagella, and another which is similarly related to the bacterial bodies; the former acts in very much higher dilutions than the latter. Another factor necessary for the phenomenon of agglutination is a proper salt content. Bordet

showed that if the clumps of agglutinated bacteria are freed from salt by washing in distilled water they become resolved, and that on the addition of some sodium chloride they are formed again, and Joos has also brought forward striking confirmatory evidence as to the necessity for the presence of salts. It is thus evident that in the phenomenon of agglutination more than one factor is concerned, and it is possible that in part it may depend on some change in the molecular relationship of the bacteria to the surrounding fluid, analogous to altered surface tension.

In the phenomenon of agglutination we have to distinguish two factors, namely, the combination of agglutinin and agglutinable substance (agglutinogen) and the actual clumping of the bacteria, and it is to be noted that whether or not the latter event follows depends on the physical condition of each of the two substances concerned. For example, in some cases when the bacteria are heated at a temperature of 65° C., for some time, they may lose the faculty of being agglutinated while they may still retain the property of combining with or binding agglutinin. Dreyer and Jex Blake have observed the remarkable fact that in certain instances on being heated to a still higher temperature they may once more become agglutinable. Another point of practical importance is that bacteria when freshly grown from the tissues are very often less agglutinable than they afterwards become when subcultured for some time.

As stated above, the agglutinins are usually placed in the second order of anti-substances, and are regarded as possessing a combining group and an active or agglutinating group. The constitution would thus be analogous to that of a toxin, and in comformity with this view Eisenberg and Volk consider that the agglutinating group may be destroyed while the combining group remains, the result being an *agglutinoid*. The evidence for this lies in the fact that when an agglutinating serum is heated to a certain temperature, not only does it lose its agglutinating action, but when the bacteria are treated with such a serum, their agglutination by active serum is interfered with, a sort of plugging up of the combining molecules having apparently taken place. Again, with agglutinating sera partially inactivated by heat or other means, what are known as "zone phenomena" occur; that is, when agglutination occurs with a given dilution of such a serum a lower dilution may fail to agglutinate, and this they suppose to be due to the interference of the union of agglutinin by agglutinoid in the greater concentration of serum. On the other hand, there are facts which cannot be brought into harmony with this view. For example, Dreyer and Jex Blake have shown that the inhibition zone may be slight when there has been much destruction of agglutinin, and on the other hand may be well marked when no weakening of the agglutinating power has resulted from the heating. The physical changes underlying such phenomena are still very obscure, but we may say at present that the existence of agglutinoids has not yet been proved.

Like immune-bodies, agglutinins are not destroyed at 55° C. (a temperature sufficient to annul bactericidal action), but different agglutinins show variations in this respect, some being affected by a temperature little above that named. The resistance to heat also varies when the serum is diluted with salt solution, and it has been shown that conditions which interfere with the coagulation of the proteins increase their resistance. Like antitoxins, agglutinins seem to be chiefly contained in the globulin fraction. Discussion has taken place as to the relation of agglutinins to immune-bodies and as to how far agglutination is an indication of immunity. It may be said that in the case of certain sera investigated it has been shown that the immune-body and the agglutinin are separate substances, but it would not be justifiable to say this is always the case. And while the agglutinative power cannot in itself be taken as the measure of the degree of immunity, agglutinins and immune-bodies are the products of corresponding reactive processes, and their formation is governed by corresponding laws. Agglutinins become fixed in definite proportion by the receptors of the bacteria—that is, the agglutinin becomes used up in the process of agglutination; and it has been shown that bacteria may take up many times the amount necessary to their agglutination—a corresponding fact to what has been established with regard to immune-bodies of hæmolytic sera. The agglutinins are specific in the sense which has been explained above (p. 561). It can be shown by the method of absorption that in an agglutinating serum there may be several agglutinins with different combining groups, some of which may be taken up by organisms allied to that which has given rise to the anti-serum (p. 390).

Besides those stated above, other phenomena have been observed in the interaction of anti-sera and the corresponding bacteria. For example, it has been shown that when certain bacteria—*e.g.*, the typhoid bacillus, b. coli, and b. proteus—are grown in bouillon containing a small proportion of the homologous serum, their morphological characters may be altered, growth taking place in the form of threads or chains which are not observed in ordinary conditions. In other instances a serum may inhibit some of the vital functions of the corresponding bacterium.

Precipitins.—Shortly after the discovery of agglutinins, Kraus showed in the case of the organisms of typhoid, cholera, and plague, that the anti-serum not only caused agglutination, but when added to a filtrate of a culture of the corresponding bacterium, produced a cloudiness and afterwards a precipitate. To the substance in the immune-serum which brought about this effect he gave the name of *precipitin*. Subsequent study

has shown that this phenomenon is closely related to agglutination; in fact several authorities consider that they represent the same reaction under different conditions—that is, that the substances which when present in the bacterial bodies give rise to agglutination, on the addition of the anti-serum, produce a precipitate when free in a fluid. To test the reaction it is accordingly necessary to have as far as possible the substance of the bacteria in solution, and for this purpose there have been introduced various methods, of which the two following may be given:—

(*a*) It is well known that in an old bouillon culture the bacteria undergo disintegration and their constituents go into solution. Accordingly, if such a culture which has been kept in the incubator for several weeks be filtered through a porcelain filter, the filtrate will contain the interacting substance or precipitinogen.

(*b*) The growth from a recent agar culture is scraped off and suspended in normal salt solution, the mixture is made feebly alkaline with soda solution and boiled for a few minutes. The mixture is then neutralised, when a precipitate forms, and is filtered through filter-paper; the filtrate contains the precipitinogen.

The precipitin test is carried out by placing in a number of small test-tubes a given amount of the bacterial filtrate along with varying quantities of the homologous anti-serum. (The latter may be obtained in the usual way by the repeated injection of dead cultures or of bacterial filtrate.) As the precipitate forms slowly the tubes should be placed in the incubator for twenty-four hours, ·5 per cent. carbolic acid being added to prevent the growth of bacteria. This precipitin reaction has now been observed in a great many bacterial diseases when the patient's serum is added to the corresponding bacterial filtrate, and has even been applied by some observers as a means of diagnosis. It is, however, less delicate and more restricted in its application than the agglutination methods.

Serum Precipitins.—This subject does not strictly belong to bacteriology, but the general phenomena are so closely allied to those just described that some reference may be made to it. When the serum of an animal is injected in repeated doses into another animal of different species, after the type of an immunisation, there appears in the serum of the animal treated a substance called precipitin, which causes a cloudiness or precipitate when added to the serum (precipitinogen) used. (In the case of rabbits, doses of 3 to 4 c.c. of the serum may be injected intraperitoneally at intervals of four to five days, a precipitin usually appearing at the end of about three weeks.) The reaction, which is a very delicate one, is conveniently observed by adding a given amount of the anti-serum, say ·05 c.c. to varying amounts of the homologous serum ·1, ·01, etc., c.c., in a series of small test-tubes, the volume being then made up

with salt solution to 1 c.c. In this way a definite reaction may be observed with ·001 c.c. of the homologous serum or even less. Here again zone phenomena, as in the case of agglutination, are met with. If the anti-serum be heated to a temperature of 75° C. for some time it acquires inhibitory properties, so that when added to a mixture of serum and anti-serum which would otherwise give a precipitate, this no longer occurs. Some observers consider that this is due to the presence of "precipitoid" in the heated anti-serum; but the observations of Welsh and Chapman show that this view is not in accordance with the facts, and indicate that the inhibition is related to a specific solvent action which the heated anti-serum has on the precipitate. They have also shown that the main mass of the precipitate is furnished by the anti-serum (precipitin), and not as is usually supposed by the protein of the homologous serum thrown down by the precipitin; this result is of high importance in connection with the action of anti-substances in general. The precipitin reaction is specific in the sense explained above. It is always most marked towards the serum of the species used in the immunisation; but while this is so, there may also be a slight reaction towards animals of allied species. An anti-human serum, for example, gives the maximum reaction with human serum, but also a slight reaction with the serum of monkeys, especially of anthropoid apes; it, however, gives no reaction with the serum of other animals. The precipitin test has thus come to be employed as a means of differentiating human from other bloods. Another interesting phenomenon is what is known as the "deviation of complement," which is produced by the combination of the two substances in the serum and anti-serum respectively. If mixtures be made according to the above method, and then a small quantity of complement, say fresh guinea-pig serum, be added, it will be found that the complement becomes absorbed, as may be shown by subsequently adding a test amount of sensitised red blood corpuscles. This deviation phenomenon is even a more delicate reaction than the precipitin test, it being often possible to demonstrate by its use from a tenth to a hundredth of the smallest amount of serum which will give a perceptible precipitate; it also is specific within the same limits.[1]

Therapeutic Use of Anti-Sera.—As will have been gathered, the chief human diseases treated by anti-sera are diphtheria, tetanus, streptococcus infection, cerebro-spinal fever, pneumonia, dysentery, plague, and snake bite. The methods of application in bacterial infections and the general results have been dealt with in treating of individual diseases. In snake bite the use of antivenenes is limited, for Lamb showed that, if a cobra with full glands bites a man, many times the minimal lethal dose are probably injected. Grave symptoms thus come on so rapidly that usually no opportunity is offered for remedial treatment by the anti-sera. Moreover, as a definite specificity exists between the poison of a particular snake and its antivenene, unless the appropriate serum is available, little effect will be produced. In

[1] For an account of precipitins, *vide* Nuttall, "Blood Immunity and Relationships," Cambridge, 1904; and of complement deviation, Muir and Martin, *Journ. of Hyg.* (1906), vi. p. 265.

cases of slight bite, however, benefit may accrue from the use of the anti-serum.

As has been shown above, antibacterial sera require for their bactericidal action a sufficiency of complement, and as this diminishes in amount when a serum is kept, the unsatisfactory results with this class of sera may be due to a deficiency of complement. Or it may be as Ehrlich suggested, that the complement naturally existing in human serum does not suit the immune-body in the anti-serum—that is, is not taken up through the medium of the latter and brought into combination with the bacterium. And there is the further possibility that even though the complement should be taken up, the zymotoxic group of the latter is not sufficiently active towards the bacterium to effect its death. In both cases it will appear that an extracellular bactericidal action cannot be produced by the particular immune-body in association with the complement of the animal in question. There is no doubt that this question of complements is one of high importance, and that both combining affinity and toxic action of complements must be considered in each case.

In such diseases as cerebro-spinal fever and pneumonia the opsonic mechanism of the infected individual may play a part in successful resistance. The favourable effects following treatment with anti-sera may thus in some cases depend on an augmentation of the opsonic powers of the body.

Theories as to Acquired Immunity.

The advances made within recent years in our knowledge regarding artificial immunity, and the methods by which it may be produced, have demonstrated the insufficiency of various theories which had been propounded. Only a short reference need be made to these. The *theory of exhaustion*, with which Pasteur's name is associated, supposed that in the body of the living animal there are substances necessary for the existence of a particular organism, which become used up during the sojourn of that organism in the tissues; this pabulum being exhausted, the organisms die out. Such a supposition is, of course, quite disproved by the facts of passive immunity. According to the *theory of retention*, the bacteria within the body were considered to produce substances which are inimical to their growth, so that they die out, just as they do in a test-tube culture before the medium is really exhausted. Such a theory only survives now in the view that antitoxins are modified toxins, the evidence

against which has already been discussed (p. 568). There then came the *humoral theory* and the *theory of phagocytosis*, but neither of these is tenable in its pure form, and the distinction between them need not be maintained. For, on the one hand, any substance with specific property in the serum must be the product of cellular activity, and, on the other hand, the facts with regard to passive immunity go far beyond the ingestive and digestive properties of phagocytes, though these cells may be in part the source of important bodies in the serum. At the present time interest centres around two theories, namely, Ehrlich's side-chain theory and Metchnikoff's phagocytic theory as further developed. These will now be discussed, and it may be noted that the ground covered by each is not coextensive. For the former deals chiefly with the production of anti-substances and its biological significance, the latter deals with the defensive properties of cells, either directly by their phagocytic activity or indirectly by substances produced by them after the manner of digestive ferments. It will be seen, however, that each has a normal process as its basis, namely, that of nutrition.

1. **Ehrlich's Side-Chain Theory.**—This may be said to be an application of his views regarding the nourishment of cells. A molecule of protoplasm (in the general sense) may be regarded as composed of a central atom group or functional-centre with a large number of side-chains, *i.e.*, atom groups with combining affinity for food-stuffs. It is by means of these latter that the living molecule is increased in the process of nutrition, and hence the name *receptors* given by Ehrlich is on the whole preferable. These receptors are of three chief kinds corresponding to the classes of anti-substances described (p. 561); the first has a single unsatisfied combining group, and merely fixes molecules of relatively simple constitution—receptor of the first order; the second has a combining group for the food molecule, and another active or zymotoxic group, which leads to some physical change in it—receptor of the second order; the third has two combining groups, one for the food molecule and another which fixes a ferment (or complement) in the fluid medium around—receptor of the third order or *amboceptor*. The last receptors come into action in the case of larger food molecules which require to be broken up by ferment-action for the purposes of the cell economy. In considering the application of this idea to the facts of acquired immunity, it must be kept in view that all the substances to which anti-substances have been obtained are, like proteins, of unknown but undoubtedly of very complex chemical constitution, and that in apparently every case the

anti-substance enters into combination with its corresponding substance antigen. The dual constitution of toxins and kindred substances, as already described (p. 195), is also of importance in this connection. Now, to take the case of toxins, when these are introduced into the system they are fixed, like food-stuffs, by their haptophorous groups to the receptors of the cell protoplasm, but are unsuitable for assimilation. If they are in sufficiently large amount, the toxophorous part of the toxin molecule produces that disturbance of the protoplasm which is shown by symptoms of poisoning. If, however, they are in smaller dose, as in the early stages of immunisation, fixation to the protoplasm occurs in the same way; and as the combination of receptors with toxin is supposed to be of firm nature, the receptors are lost for the purposes of the cell, and the combination R.-T. (receptor + toxin) is shed off into the blood. The receptors thus lost become replaced by new ones, and when additional toxin molecules are introduced, these new receptors are used up in the same manner as before. As a result of this repeated loss, the regeneration of the receptors becomes an over-regeneration, and the receptors formed in excess appear in the free condition in the blood stream and then constitute antitoxin molecules. There are thus three factors in the process, namely, (1) fixation of toxin, (2) over-production of receptors, (3) setting free of receptors produced in excess. Accordingly these receptors which, when forming part of the cell protoplasm, anchor the toxin to the cell, and thus are essential to the occurrence of toxic phenomena, in the free condition unite with the toxin, and thus prevent the toxin from combining with the cells and exerting a pathogenic action. The three orders of receptors, when separated from the cells, thus give the three kinds of anti-substances. Ehrlich did not state what cells are specially concerned in the production of anti-substances, but from what has been stated it is manifest that any cell which fixes a toxin molecule, for example, is potentially a source of antitoxin. Cells, to whose disturbance, resulting from the fixation of toxin, characteristic symptoms of poisoning are due, will thus be sources of antitoxin, *e.g.*, cells of the nervous system in the case of tetanus, though the cells not so seriously affected by toxin fixation may act in the same way. The experimental investigation of the source of antitoxins has, however, yielded little result, and no definite statement can be made on the subject.

When we come to consider how far Ehrlich's theory is in harmony with known facts, we find that there is much in its favour. In the first place, it explains the difference between

active and passive immunity, *e.g.*, difference in duration, etc.; in the former the cells have acquired the habit of discharging anti-substances, in the latter the anti-substances are simply present as the result of direct transference. It is also in harmony with the action of antitoxins, etc., as detailed above, and especially it affords an explanation of the multiplicity of anti-substances. For, if we take the case of antitoxins, we see that this depends upon the combining affinity of the toxin for certain of the cells of the body, and this again is referred back to the complicated constitution of living protoplasm. Furthermore, the biological principle involved is no new one, being simply that of over-regeneration after loss. It would appear likely that the integrity of the functional centres of the protoplasm molecules would be essential to the satisfactory production of side-chains, and this would appear in accordance with the fact that antitoxin formation occurs most satisfactorily when there is no marked disturbance of the health of the animal.

It is to be noted, however, that it does not explain active immunity apart from the presence of anti-substances in the serum. For example, an animal may be able to withstand a much larger amount of toxin than could be neutralised by the total amount of antitoxin in its serum. This might theoretically be explained by supposing a special looseness of the cell receptors so that the toxin-receptor combination became readily cast off. The question, however, arises whether there may not be really an increased resistance of the cells to the toxophorous actions. An observation made by Meyer and Ransom (*vide* p. 432) is also difficult of explanation, according to the view that antitoxin is formed by the cells with which the toxin combines and on which it acts. They found that in an animal actively immunised against tetanus and with antitoxin beginning to appear in its blood, the injection of a single M.L.D. of tetanus toxin into a peripheral nerve brought about tetanus with a fatal result. On the other hand, the injection of antitoxin into the sciatic nerve above the point of injection of toxin prevented the latter from reaching the cells of the cord. One can scarcely imagine an explanation of these facts if antitoxin molecules were in process of being shed off by the cells of the nervous system. There is also the fact, very difficult of explanation according to the theory of regeneration of receptors, or, indeed, according to any theory, that the amount of anti-substance produced, as tested by its combining equivalent, may be many times what would correspond to the amount of antigen injected. Further, when the serum of an animal contains

a large amount of antitoxin, how does the additional toxin injected reach the cells in order to influence them as we know it does? This also is difficult to understand, unless the toxin has a greater affinity for the receptors in the cells than for the free receptors (antitoxin) in the serum. A supersensitiveness of the nerve-cells of an animal to tetanus toxin, sometimes observed even when there is a large amount of antitoxin in the serum, has been often brought forward as an objection. But this also may perhaps be explained by there having occurred a partial damage of the cell protoplasm by the toxic action in the process of immunisation—an explanation which, of course, demands that in some way the freshly introduced toxin may reach the cells in spite of the antitoxin in the blood, or it may belong to the group of anaphylactic phenomena described below (p. 595). Further investigation alone will settle these and various other disputed points, and may remove many of the apparent objections. At present we may say, however, that Ehrlich's theory is the only one which even attempts to explain the cardinal facts of this aspect of immunity.

2. **The Theory of Phagocytosis.**—This theory, brought forward by Metchnikoff to explain the facts of natural and acquired immunity, has been of enormous influence in stimulating research on the subject. Looking at the subject from the standpoint of the comparative anatomist, he saw that it was a very general property possessed by certain cells throughout the animal kingdom, that they should take up foreign bodies into their interior and in many cases digest and destroy them. On extending his observations to what occurred in disease, he came to the conclusion that the successful resistance of an animal against bacteria depended on the activity of certain cells called phagocytes. In the human subject he distinguished two chief varieties, namely—(*a*) the microphages, which are the "polymorpho-nuclear" finely granular leucocytes of the blood; and (*b*) the macrophages, which include the larger hyaline leucocytes, endothelial cells, connective tissue corpuscles, and, in short, any of the larger cells which have the power of ingesting bacteria. Insusceptibility to a given disease is indicated by a rapid activity on the part of the phagocytes, different varieties being concerned in different cases,—an activity which may rapidly destroy the bacteria and prevent even local damage. If the organisms are introduced into the tissues of a moderately susceptible animal, there occurs an inflammatory reaction with local leucocytosis, which results in the intracellular destruction of the invading organisms. Phagocytosis was regarded by

Metchnikoff as the essence of inflammation. He also showed that the bacteria may be in a living and active state when they are ingested by leucocytes. On the other hand, he found that in a susceptible animal phagocytosis did not occur or was only imperfect. He also showed that when a naturally susceptible animal was immunised, the process was accompanied by the appearance of an active phagocytosis. The ingestion of bacteria by phagocytes is undoubtedly a phenomenon of the greatest importance in the defence of the organism. It is known that amœbæ and allied organisms have digestive properties which are specially active towards bacteria, and from what can be directly observed, as well as indirectly inferred, there can be no doubt that such a faculty is also possessed by the phagocytes of the body. Thus bacteria within these cells are in a position favourable to their destruction, and do in many instances become destroyed. In fact, observations on phagocytosis *in vitro* show that such destruction may in the case of some organisms occur so rapidly that the actual number observable in the leucocytes is no indication of the activity of the process. In other instances, *e.g.*, in gonorrhœa, the ingested organisms would appear to survive a considerable time without undergoing change. Undoubtedly phagocytosis is of the highest importance in active immunity, as by its means organisms which would not undergo an extracellular death may be killed off. In the process of immunisation of a susceptible animal we see a negative or neutral chemiotaxis becoming replaced by positive chemiotaxis. This was explained by Metchnikoff as due to an education or stimulation of the phagocytes. The recent work on opsonins shows, however, that this is not the case, as leucocytes from an immunised animal are as a rule not more active in this direction than those of a normal animal, the all-important factor being the development of an opsonin in the immune animal. Thus this phase of immunity comes to be merely an aspect of the action of anti-substances in general.

The digestive ferments of phagocytes or *cytases* are, according to Metchnikoff, retained within the cells under normal conditions, but are set free when these cells are injured—for example, when the blood is shed. They then become free in the serum by the breaking up of the cells—the process known as phagolysis—and they then constitute the alexins, or complements of Ehrlich. Of these, as has already been said, Metchnikoff believed there are probably two kinds—one called *macrocytase*, contained in the macrophages, which is specially active towards the formed elements of the animal body, protozoa, etc.; and the other,

microcytase, contained within the polymorpho-nuclear leucocytes, which has a special digestive action on bacteria. It is the microcytase which gives blood serum its bactericidal properties. It appears to us, however, that Metchnikoff went too far in distinguishing the activities of the two classes of cells so sharply as he did.

When the properties of antibacterial sera, as above described, are considered in relation to phagocytosis, Metchnikoff gave the following explanation. He admitted that the immune-body is fixed by the bacteria (or red corpuscles, as the case may be), though he did not state that a chemical combination takes place; hence he called it a fixative (*fixateur*). The immune-bodies are to be regarded as auxiliary ferments (*ferments adjuvants*) which aid the action of the alexin. Unlike the latter, however, they are formed in excess during immunisation and set free in the serum. He compared their action to that of enterokinase, a ferment which is produced in the intestine and which aids the action of trypsin. Thus, when the bacteria have fixed the immune-body, their digestion is facilitated either within the phagocytes, or outside of them when the alexin has been set free by phagolysis. He, however, maintained that extracellular digestion or lysogenesis does not take place without the occurrence of phagolysis. The source of immune-bodies is, in all probability, also the leucocytes, as these substances are specially abundant in organs rich in such cells—spleen, lymphatic glands, etc.; here again the mononuclear leucocytes are probably the source of the immune-bodies concerned in hæmolysis, the polymorpho-nuclear leucocytes the source of those concerned in bacteriolysis. Although the immune-bodies are usually set free in the serum, this is not always the case; sometimes they are contained in the cells, and this probably occurs when there is a high degree of active immunity against bacteria without a serum having an antibacterial action, the powers of intracellular digestion being in such cases increased. In this way the facts of immunity can be explained so far as these concern the destruction of bacteria.

Metchnikoff's work has less direct bearing on the production of antitoxins. He admitted the fixation of the toxin by the antitoxin to form a neutral compound, and he apparently considered that leucocytes may also be concerned in the production of antitoxins. Apart, however, from antitoxin formation, he considered the acquired resistance of the cells themselves of high importance in toxin immunity.

When we consider Metchnikoff's theory as thus extended to

cover recently established facts, it must be admitted that it affords a rational explanation of a considerable part of the subject, though the elucidation of the chemiotactic phenomena during immunisation as explained above detracts from the importance which he attached to the leucocyte. It, however, does not afford explanation of the multiplicity and specificity of antitoxins; on the other hand, it is more concerned with the cells of the body as destroyers or digesters of bacteria. As regards the subject of antibacterial sera, the results of these two workers may be said to be in harmony in some of the fundamental conceptions. And it is of interest to note that Metchnikoff, starting with the phenomena of intracellular digestion, arrived at the giving off of specific ferments by phagocytes; whilst Ehrlich, from his first investigations on the constitution of toxins, reached an explanation of antitoxins and immune-bodies also with a theory of cell-nutrition as its basis.

Natural Immunity.

We have placed the consideration of this subject after that of acquired immunity, as the latter supplies facts which indicate in what direction an explanation of the former may be looked for. There may be said to be two main facts with regard to natural immunity. The first is, that there is a large number of bacteria —the so-called non-pathogenic organisms—which are practically incapable, unless perhaps in very large doses, of producing pathogenic effects in any animal; when these are introduced into the body they rapidly die out. This fact, accordingly, shows that the animal tissues generally have a remarkable power of destroying living bacteria. The second fact is, that there are other bacteria which are very virulent to some species of animals, whilst they are almost harmless to other species; the anthrax bacillus may be taken as an example. Now it is manifest that natural immunity against such an organism might be due to a special power possessed by an animal of destroying the organisms when introduced into its tissues. It might also possibly be due to an insusceptibility to, or power of neutralising, the toxins of the organism, for the study of the various diseases shows that the toxins (in the widest sense) are the weapons by which morbid changes are produced, and that toxin-formation is a property common to all pathogenic bacteria. As a matter of fact, however, natural immunity is in most cases one against *infection*, *i.e.*, consists in a power possessed by the animal body of destroying the living bacteria when introduced into its tissues: such a

power may exist though the animal is still susceptible to the separated toxins. We shall now look at these two factors separately.

1. *Variations in Natural Bactericidal Powers.*—The fundamental fact here is that a given bacterium may be rapidly destroyed in one animal, whereas in another it may rapidly multiply and produce morbid effects. The special powers of destroying organisms in natural immunity have been ascribed to (*a*) phagocytosis, and (*b*) the action of the serum.

(*a*) The chief factors with regard to phagocytosis have been given above. The bacteria in a naturally immune animal, for example, the anthrax bacillus in the tissues of the white rat, are undoubtedly taken up in large numbers and destroyed by the phagocytes, whereas in a susceptible animal this only occurs to a small extent; and Metchnikoff showed that they are taken up in a living condition, and are still virulent when tested in a susceptible animal. Variations in phagocytic activity are found to correspond more or less closely with the degree of immunity present, but are probably in themselves capable of explanation. The fundamental observations of Wright and Douglas show that, in many cases at least, leucocytes do not ingest organisms to any extent in normal saline solution, and that this is not due to the medium in which they are, is readily shown by subjecting the organisms to the action of fresh serum and then washing them; thereafter, they are rapidly taken up by the leucocytes in salt solution. In most cases this result is due to the labile opsonin of normal serum, which has combining affinities for a great many organisms, as already stated. In other cases more specific substances may be concerned. But the all-important fact is that whether phagocytosis occurs or not appears to depend upon certain bodies in the serum. As yet we cannot say whether the phagocytosis in a given serum, observed according to the opsonic technique, always runs parallel with phagocytosis in the tissues of the animal from which the serum has been taken. This is a subject on which extended observations are necessary. But whether or not phagocytosis *in vivo* corresponds with that *in vitro* it is probably to be explained in the same way; that is, it probably depends upon the content of the serum. The composition of the latter, no doubt, is the result of cellular activity, and in this the leucocytes themselves are in all probability concerned, but the movements and phagocytic activity of these cells seem to be chiefly if not entirely controlled by their environments. Ingestion is, however, only the first stage in the process; intracellular destruction is the second, and is of equal importance.

What may be called intracellular bactericidal action probably varies in the case of leucocytes of different animals, but regarding this our knowledge is deficient, and, further, bacteria may sometimes survive the cells which have ingested them. In other instances the organisms do not appear to suffer from their intracellular position; an example of this is afforded in the case of gonococci.

(*b*) When it had been shown that normal serum possessed bactericidal powers against different organisms, the question naturally arose as to whether this bactericidal power varied in different animals in proportion to the natural immunity enjoyed by them. The earlier experiments of Behring appeared to give grounds for the belief that this was the case. He found, for example, that the serum of the white rat, which has a remarkable immunity to anthrax, had greater bactericidal powers than that of other animals investigated. Further investigation, however, has shown that this is not an example of a general law, and that the bactericidal action of the serum does not vary *pari passu* with the degree of immunity. In some cases non-pathogenic and also attenuated pathogenic bacteria can be seen to undergo rapid solution and disappear when placed in a drop of normal serum; in the case of many pathogenic organisms, however, the serum has no direct bactericidal effect at all. The bactericidal action of the serum was specially studied by Nuttall, and later by Buchner and Hankin, who believed that the serum owed its power to certain substances in it derived from the spleen, lymphatic glands, thymus, and other tissues rich in leucocytes. To these substances Buchner gave the name of *alexins*; as already explained, they correspond with Metchnikoff's cytases and Ehrlich's complements described above. They can be precipitated by alcohol and by ammonium sulphate, and in this respect and in their relative lability correspond with enzymes or unorganised ferments. Variations in bactericidal power of the serum as tested *in vitro*, however, do not explain the presence or absence of natural immunity against a living bacterium. In some cases, for example, it has been found to be considerable, while the organisms flourish in the body and the animal has no immunity. In such a case Metchnikoff held that there occurs in the living body no liberation of alexins by the phagocytes, and hence no bactericidal action such as occurs when the blood is shed. In the case of the hæmolytic action of a normal serum, it has been shown in many instances that in addition to complement a natural immune-body is also concerned (p. 576), and this would appear to be the rule; the process being analogous to

what is seen in the case of an artificially developed hæmolytic serum. In certain instances an analogous condition appears to obtain in a normal bactericidal serum. For example, the dog's serum heated at 58° C. contains a natural immune-body to anthrax which can be activated by the addition of normal guinea-pig's serum so as to produce a bactericidal action, though the latter is by itself without any such effect. At present, however, the possibility of bactericidal action by complement alone cannot be excluded, as it appears to combine with many bacteria without any intermediary. Further work is necessary to determine whether all the facts regarding natural immunity are explainable by the opsonic and bactericidal properties of the serum.

2. *Variations in Natural Susceptibility to Toxins.*—We must here start with the fundamental fact, incapable of explanation, that toxicity is a relative thing, or, in other words, that different animals have different degrees of resistance or non-susceptibility to toxic bodies. In every case a certain dose must be reached before effects can be observed, and up to that point the animal has resistance. This natural resistance is found to present very remarkable degrees of variation in different animals. The great resistance of the common fowl to the toxin of the tetanus bacillus may be here mentioned (*vide* p. 430), and large amounts of this poison can be injected into the scorpion without producing any effects whatever; the high resistance of the pigeon to morphia is a striking example in the case of vegetable poisons. This variation in resistance to toxins applies also to those which produce local effects, as well as to those which cause symptoms of general poisoning. Instances of this are furnished, for example, by the vegetable poisons ricin and abrin, by the snake poisons, and by bacterial toxins such as that of diphtheria. We must take this natural resistance for granted, though it is possible that ere long it will be explained.

According to Ehrlich's view of the constitution of toxins, it might be due to the want of combining affinity between the tissue cells and the haptophorous group of the toxin; or, on the other hand, supposing this affinity to exist, it might be due to an innate non-susceptibility to the action of the toxophorous group. Certain investigations have been made in order to determine the combining affinity of the nervous system of the fowl with tetanus toxin, as compared with that obtaining in a susceptible animal, but the results have been somewhat contradictory. Accordingly, a general statement on this point cannot at present be made, though in all probability variations in the susceptibility to the toxophorous group will be found to play a

very important part. It has been shown by Muir and Browning by means of hæmolytic tests that the toxic activity of complement, after it has been fixed to the corpuscles, varies very much ; in some instances an amount of complement, which would rapidly produce complete lysis of one kind of corpuscle, may have practically no effect on another, even though it enters into combination. These results are of importance in demonstrating how the corresponding cells of different animals may vary in sensitiveness to toxic action.

Supersensitiveness or Anaphylaxis.

Under this heading are to be grouped a number of phenomena which in their character and results appear to present a striking contrast to the state of immunity, yet in their essential nature are probably closely allied to the latter condition. Like immunity, supersensitiveness may be *natural* or *acquired*. It has long been recognised that the ingestion of certain substances, *e.g.*, shell-fish, strawberries, etc., by normal individuals is sometimes followed by constitutional disturbances, and more recently it has been found that in a small proportion of individuals the injection of a small amount of foreign serum may give rise to constitutional disturbances. There is therefore a natural supersensitiveness to these substances. The greatest importance, however, from the practical point of view, is in regard to acquired supersensitiveness in the process of serum treatment. The general fact is that repeated injections of certain substances in sub-toxic or non-toxic doses—a suitable interval of time elapsing between the injections—may be followed by markedly toxic or even fatal symptoms, and a similar result may follow repeated injections of substances which are practically non-toxic in a single dose. The substances which have been found to have the property of calling forth this condition are of various kinds, including bacteria and their toxins, animal poisons, and a great many foreign proteins, *e.g.*, those of serum, milk, egg albumin, etc., and it is to be noted that they belong to the group of substances which can act as antigens. Probably only proteins originate supersensitiveness ; and, just as tolerance, say to drugs, is to be distinguished from immunity, so accumulative action is to be distinguished from supersensitiveness. Of the latter condition the earliest example observed was probably the special susceptibility of tubercular patients to the action of tuberculin, to which reference has already been made (p. 290), and to this and like conditions the term *allergy* is often applied. At a comparatively early date also it was found, in the case of diphtheria and

tetanus toxins, that in certain instances the injection of a minute dose followed by another at a suitable interval might be attended by serious results; and that this was not an example of accumulative action, was shown by the fact that the sum of the doses might amount to only a fraction of a lethal dose. Richet investigated a similar phenomenon in the case of a toxic substance obtained from the tentacles of actiniæ, to which, from its action, he gave the name of "congestin." He found that a certain time-interval between the injections was necessary; that after the second injection the symptoms occurred with remarkable suddenness, and that they appeared to be practically independent of the size of the first dose. He applied the term *anaphylaxis* to the supersensitive condition, and this has passed into general use; he found also that the condition lasted several weeks at least. Arthus found that after repeated injections of horse serum in rabbits a stage was reached at which an additional subcutaneous injection produced marked œdema and even necrosis, while an intravenous injection, harmless to an untreated animal, brought about a fatal result. The period of active research on the subject, however, may be said to date from the discovery of what is now known as the "phenomenon of Theobald Smith." This observer found that guinea-pigs which had been treated with a neutral mixture of diphtheria toxin and antitoxin might, after a certain interval of time, succumb on being injected with a quantity of normal horse serum. It was afterwards shown—especially by the researches of Otto and of Rosenau and Anderson—that the sensitising agent had really nothing to do with the toxin or antitoxin, but was contained in the normal serum.

After this brief review we may consider some of the phenomena of serum anaphylaxis, as it is now called. In its study horse serum has been chiefly employed, but other sera are also efficient, and the guinea-pig is the most suitable test animal; the rabbit has also been used, but its relative susceptibility is less than a hundredth of that of the guinea-pig. In the case of mice it is difficult if not impossible to bring about serum anaphylaxis. There is first of all the sensitising injection; a guinea-pig is injected subcutaneously with a minute quantity, *e.g.*, ·001 c.c. of horse serum, though even ·000,001 c.c. has been found sufficient; other methods of injection may also be employed. After a certain number of days, usually ten as a minimum, anaphylaxis has been established, and the test for this is usually made by injecting subcutaneously 5 c.c. of horse serum. In the anaphylactic animal severe symptoms occur; restlessness

and hyperalgesia are followed by evidence of collapse, the temperature falls markedly, urine and fæces are passed, the heart's action becomes weak and the respiration embarrassed: in fatal cases respiration stops before the heart's action ceases. The intravenous injection of a smaller amount of serum brings about the same result more rapidly. It is to be noted that the minimum amount of serum necessary to bring about the symptoms of fatal anaphylactic shock is much greater, about a thousand times greater, than the original sensitising dose; and that while anaphylaxis is not fully established till about the tenth day, it occurs gradually,—not by crisis,—as can be shown by disturbance of the temperature at a much earlier period on re-injection of serum. Anaphylaxis has the character of specificity, apparently within corresponding limits to immunity (p. 561)—that is, it is manifested only on the re-injection of the same protein substance as that used in the first instance. There is also a passive anaphylaxis, as is shown by the fact that if a certain amount of the serum of an anaphylactic guinea-pig be injected into a normal one, the latter becomes anaphylactic, so that the characteristic symptoms appear in it when the test amount of horse serum is injected. In most instances an interval of some hours at least must, however, elapse between the injections in the guinea-pig (Otto); if the two injections are made at the same time there is usually no result. In the rabbit and dog, however, the symptoms appear almost at once after the two injections. Passive anaphylaxis usually disappears after a few weeks at longest, whereas active anaphylaxis has been observed after more than two years; here also there is an analogy between anaphylaxis and immunity. Another interesting observation has been made, namely, that the young of anaphylactic mothers may also be anaphylactic, and the condition may last for some time after birth. It is also possible to produce a condition of anti-anaphylaxis. If, for example, the sensitising dose of horse serum is injected, and then before anaphylaxis is established (*i.e.*, some time before the tenth day) another injection of a considerable quantity of serum is made, anaphylaxis does not appear, and the animal is non-susceptible to further injections of small doses for a considerable period of time. On the other hand, if anaphylaxis exists, the serious effects may be avoided by the injection of a small dose of serum, insufficient in itself to bring about typical symptoms, and then by the injection of graduated increasing doses.

With regard to the mechanism underlying the phenomena described, practically all observers are agreed that there is a

profound toxic affection of the nervous system; but it is still an open question to what extent the action is central, to what extent peripheral; both modes are probably concerned. A great fall in the blood-pressure is an important phenomenon in the dog and rabbit, and is due chiefly to a vaso-dilatation in the abdomen, which can be only partly counteracted by the administration of atropine or barium chloride. It has been pointed out by Auer and Lewis that in the case of guinea-pigs there occurs a spasm of the muscle fibres in the fine bronchi and alveolar passages, the chest-wall being fixed in full inspiration at the time of death. Amelioration of symptoms by the administration of ether or chloral, or by lowering the intracranial pressure by trephining, would, on the other hand, point to the importance of a central action.

From the facts above detailed it is manifest that at least two substances are concerned in the production of the toxic phenomena, one present in the serum injected (antigen), which is in itself non-toxic, and another developed in response to the injection of the antigen, usually called the "antiphylactic reaction-body," which is also non-toxic; the union, or at least the co-operation, of these two leads to the toxic effects. Thus Richet considers that the antigen gives rise to the production of a body which he calls toxogenin and that these unite to produce the active poison "apotoxin." The transference of the toxogenin by the injection of the serum of an anaphylactic animal into a fresh animal would accordingly explain the phenomena of passive anaphylaxis. The most detailed analysis of the subject has, however, been given by Friedberger, who explains the phenomena as resulting from the process of digestion of protein, introduced parenterally; the toxic agent in anaphylaxis is a disintegration product of protein. As is well known, the injection of a foreign protein in this way gives rise to an anti-substance, for example, a precipitin, and the combination of the two has the property of fixing complement. Now Friedberger has shown that the action of complement on a serum precipitate (antigen + precipitin) produces a toxic body, which on being separated from the precipitate by the centrifuge, and injected into an animal, causes all the symptoms of anaphylaxis; this body he calls *anaphylatoxin*. He has also defined the quantitative relationships subsisting between antigen, anti-substance, and complement, which give rise to the greatest amount of anaphylatoxin. If the proteid disintegration is accelerated and carried to a further point, then non-toxic substances are formed. He has also shown that anaphylatoxin is produced by the action of complement on

bacteria treated with their homologous serum, and also by the action of normal serum alone on bacteria and even on coagulated serum. The phenomena of anaphylaxis therefore constitute an accident, as it were, in the process of immunisation, which is to be regarded as a reaction of the living organism against the introduction of foreign proteins. In this way there is also explained the marked fall in complement in anaphylactic shock, which has been found to occur by Friedberger, Scott, and others. Friedberger holds that though the various anaphylatoxins are similar, or, at least, closely allied substances, there is nothing specific in their nature; what is specific is merely the union of antigen and anti-substance, the combination when acted upon by complement giving rise to the poisonous substance.

Besredka considers that the sensitising and the toxic factors in the horse serum are not one and the same. He finds that serum heated to a certain temperature may still have the power of inducing the condition of anaphylaxis, but has lost the power of bringing about the toxic phenomena when injected into an anaphylactic animal. This result has, however, been explained by others as being due to the fact that the sensitising dose is so much smaller than the toxic dose (*vide supra*) on re-injection; accordingly the effect of heat may be to reduce the latter below the fatal limit without having a corresponding effect on the sensitising dose. On the other hand, Gay and Southard do not believe in the theory of a reaction body. They consider that the condition depends on the presence of a substance in the serum which they call anaphylactin, and which persists in the blood of the guinea-pig for a long period of time. This acts as a slight irritant to the nerve-cells, and produces in them an increased affinity for certain molecules in the serum. Accordingly, when the second injection is made, the rapid combination of these molecules with the cells results in the disturbances described. This view has, however, received little support, and there are various facts against it, especially in relation to the transference of anaphylaxis.

It is still an open question as to what extent the phenomena of anaphylaxis just described are of the same nature as the supersensitiveness or allergy manifested by patients suffering from disease to the products of the corresponding organism, *e.g.*, to tuberculin, mallein, etc. (pp. 290, 316); though in all probability they are at least similar in essence. It was held for some time as a distinction that this supersensitiveness in infections to bacterial products could not be transferred to another animal, but recent observations show that in certain circumstances this is possible in the case of tuberculin. According to some observers, the phenomena of supersensitiveness of tubercular patients to tuberculin is due to the combination of the injected antigen with molecules of anti-substance resident in the tissue cells, the so-called "sessile receptors"; but, according to Friedberger, the

facts can be equally well explained by the combination, which occurs either locally or generally, of the antigen with anti-substance *in the serum*, which combination when acted upon by complement gives rise to the poisonous substance. At present it is not possible to make a definite statement on the subject. There is no doubt that the supersensitive condition must play an important part in the clinical manifestations of many diseases. For example, the sensitiveness of tubercular patients to tuberculin shows that the symptoms in this disease are evidently produced by the absorption from the tubercular foci of a smaller amount of toxin than would be necessary to produce effects in a normal individual. And the sensitiveness of the conjunctiva in typhoid fever to the products of the bacillus suggests that in this disease also supersensitiveness plays an important part. It is also possible that the repeated absorption of bacterial products may lead to toxic symptoms when tested in the usual manner, whilst they prove harmless by single injections. There is thus a good deal in favour of Friedberger's view that anaphylaxis corresponds to an "acute infection," whereas ordinary infection is of the nature of a gradual and protracted anaphylaxis. The essential factor in antibacterial immunity is a disintegration of the bacterial protoplasm, and the essential agents in anaphylaxis are the split-products of proteins. The toxic agents in many bacterial infections may thus be of common nature; what constitutes their apparently specific characters may depend upon the site of the organisms, the mode of absorption of their products, etc. The phenomena of anaphylaxis may thus in part explain the symptoms of a disease, and may, on the other hand, be an accidental result of the process of immunity. The phenomena of hay fever probably belong to the same class, being the result of acquired anaphylaxis to a vegetable protein, and some evidence has been brought forward that puerperal eclampsia is produced by the absorption of proteins from the placenta, which have the property of establishing an anaphylactic state.

The Serum Disease in Man.—This is another example of anaphylaxis. There is here also a period of incubation, of eight to twenty days on the average; after which, in a certain proportion of cases (in about 20 per cent.) after the injection of a fairly large amount of horse serum, a group of characteristic symptoms appear. There may be as prodromal symptoms, swelling and tenderness at the site of injection, and in the corresponding lymphatic glands, and thereafter general exanthemata appear. These are usually of an urticarial type, but may be erythematous

or morbilliform. There is usually moderate pyrexia of a remittent type, and sometimes œdema and slight albuminuria are present; occasionally there are pains in the joints; there is also often leucopenia, due to a fall in the number of polymorphonuclear leucocytes. These symptoms last for a few days and then disappear. Such are the phenomena of the serum disease after a single injection of the foreign serum. There are, however, two other types of reaction described by v. Pirquet and Schick, namely, the *immediate* and the *accelerated* reactions. The immediate reaction is seen when a large dose of serum has been administered and then after a certain interval of time another dose of serum is injected. This interval is usually from twelve days to eight weeks, though sometimes as long as six months. The symptoms of the immediate reaction, which appear shortly after the injection, or at least within twenty-four hours, are an intense œdema locally, general exanthemata and pyrexia, though the general phenomena are often little marked. The symptoms pass off comparatively quickly, usually within twenty-four hours. The accelerated reaction is also seen after a second injection, and it may occur from six weeks up to many months after the first injection. In the case of the accelerated reaction there is an incubation period, but it is shorter than in the case of the first injection, being usually from five to seven days; the symptoms resemble those in the ordinary reaction as described above, but are of rather more acute onset and last a shorter time. In the interval from about the sixth week to the sixth month, there may occur both the immediate reaction, and also a few days later an accelerated reaction.

The phenomena of the serum disease in all probability depend upon the development of a reaction-body or anti-substance, as above described. We suppose that the serum antigens gradually disappear from the body after the injection; from about the eighth day onward anti-substances appear in the blood in large amount, and if antigens are still present in proper amount, the combination of the two, probably acted on by complement, brings about the phenomena described. Manifestly, if the antigens have disappeared before the anti-substances appear in quantity, there will be no symptoms. At a later period anti-substances will be present alone in the serum, and then the injection of fresh antigens brings about an immediate reaction. After the anti-substances have disappeared, the injection of fresh serum causes no immediate reaction, but the mechanism of reaction has been stimulated by the first injection; anti-substances thus appear more quickly after the second injection,

hence the reaction is accelerated as compared with the reaction after the first injection.

Practical Results—Desensitisation.—In view of the common use of curative serum, anaphylaxis has come to have considerable practical importance, especially in connection with intravenous injection, as by this route the dangerous dose is a fraction of that by subcutaneous injection. With regard to the possibility of there being a primary or natural supersensitiveness, inquiry should be made as to tendency to asthma or hay fever, or sensitiveness to the presence of horses in the vicinity, as these have been found to be associated conditions, and the existence of Graves' disease has been recorded as another. Then with regard to the acquired variety, information should be obtained as far as possible regarding previous serum injections. The existence of supersensitiveness can, however, be demonstrated by the test for skin "allergy." A small quantity, say ·25 c.c., of sterile horse serum is injected by a hypodermic needle into the dermis—not subcutaneously. The minute local swelling which results from the presence of the fluid soon passes off. But in the case of a positive reaction there occurs, usually within five to thirty minutes, an urticarial patch, which may be followed by a distinct vesicle and is often surrounded by an erythematous area, an inch or more in diameter. If no reaction occurs within forty minutes the absence of supersensitiveness may be inferred. If a positive reaction is obtained, means must be taken to desensitise the patient, *i.e.*, to produce anti-anaphylaxis; and this is accomplished by introducing initial small and then gradually increasing doses of serum. In the hospital of the Rockefeller Institute, where large intravenous doses of serum are given in the treatment of pneumonia, the initial desensitising dose is ·025 c.c. given subcutaneously, and this amount is doubled every half-hour. If no reaction follows the administration of 1 c.c., the subsequent doses are given intravenously, commencing with ·1 c.c. and doubling the dose every half-hour till 25 c.c. in all have been given in these small doses. Such a method, however, takes a considerable number of hours and is not justifiable in a case of tetanus, where a large amount of serum should be given intravenously or intrathecally as soon as possible. The following method, given in the War Office memorandum, should be followed: 5 c.c. of the anti-serum are diluted with 50 c.c. of normal salt solution. Of the mixture 1 c.c. is injected intravenously; this is followed four minutes later by 3 c.c., two minutes later by 10 c.c., and two minutes later again by 25 c.c. Then after ten to fifteen minutes the full dose may be given

intravenously or intrathecally. The doses mentioned are most suitably given by the gravitation method. If any anaphylactic symptoms appear, the administration must be temporarily stopped and then cautiously resumed. The chief symptoms are dyspnœa, with pallor or cyanosis, fall in the blood pressure, with feeble pulse, asthmatic symptoms, with cough, and sometimes vomiting. Adrenalin and atropine are the most efficient drugs. In all cases the administration of serum by the methods mentioned should be carried out slowly and with caution. Anaphylaxis is sometimes a real danger, but the risks, when we take into account the necessity for the prompt treatment of tetanus, have been exaggerated. We may add that the repeated subcutaneous injections for preventive purposes of the usual quantity of 3 c.c. of serum are unattended by any danger. It may also be stated that in relation to anaphylaxis it is only the *amount of serum* which matters—the antitoxic value is not a factor.

APPENDIX A.

SMALLPOX AND VACCINATION.

SMALLPOX is a disease to which much study has been devoted owing, on the one hand, to the havoc which it formerly wrought in Europe,—a havoc which at the present day it is difficult to realise,—and, on the other hand, to the controversies which have arisen in connection with the active immunisation against it introduced by Jenner. Though there is little doubt that a *contagium vivum* exists, the etiological relationship of any particular organism to smallpox has still to be proved; and with regard to Jennerian vaccination, it is only the advance of bacteriological knowledge which enables us to understand the principles which underlie the treatment, and which furnishes methods whereby the vexed questions concerned may be satisfactorily settled.

Jennerian Vaccination.—Up to Jenner's time the only means adopted to mitigate the disease had been by inoculation (by scarification) of virus taken from a smallpox pustule, especially from a mild case. By this means a mild form of the disease was often originated. It had previously been known that one attack of the disease protected against future infection, and that the mild attack produced by inoculation also had this effect. This inoculation method had long been practised in various parts of the world, and had considerable popularity all over Europe during the eighteenth century. Its disadvantage was that the resulting disease, though mild, was still infectious, and thus might be the starting-point of a virulent form among unprotected persons. Jenner's discovery was published when inoculation was still considerably practised. It was founded on the popular belief that those who had contracted cowpox from an affected animal were insusceptible to subsequent infection from smallpox. In the horse there occurs a disease known as horsepox, especially tending to arise in wet, cold springs, which consists in an inflammatory condition about the hocks, giving

rise to ulceration. Jenner believed that the matter from these ulcers, when transferred by the hands of men who dressed the sores to the teats of cows subsequently milked by them, gave rise to cowpox in the latter. This disease was thus, in his opinion, identical with horsepox in epidemics of which it had its origin. Cowpox manifests itself as a papular eruption on the teats; the papules become pustules; their contents dry up to form scabs, or more or less deep ulcers occur at their sites. From such a lesion the hands of the milkers may become infected through abrasions, and a similar local eruption occurs, with general symptoms in the form of slight fever, malaise, and loss of appetite. It is this illness which, according to Jenner, gives rise to immunity from smallpox infection. He showed experimentally that persons who had suffered from such attacks did not react to inoculation with smallpox; and further, that persons to whom he communicated cowpox artificially were similarly immune. The results of Jenner's observations and experiments were published in 1798 under the title, *An Inquiry into the Causes and Effects of the Variola Vaccinæ*. Though from the first Jennerian vaccination had many opponents, it gradually gained the confidence of the unprejudiced, and became extensively practised all over the world, as it is at the present day.

The so-called vaccine lymph which contains the protecting agent is the serous exudate of the cowpox vesicle. When such lymph is used for inoculating calf from calf by *passage* a continuous supply of a product of very constant potency is obtained; this is the usual source of the lymph used for human vaccination. By its use immunity against smallpox is conferred on the vaccinated individual. It has been objected that some of the lymph which has been used has been derived from calves inoculated, not with cowpox, but with human smallpox. It is possible that this may have occurred in some of the strains in use shortly after the publication of Jenner's discovery, but most of the modern strains have probably been derived originally from cowpox. The most striking evidence in favour of vaccination is derived from its effects among the staffs of smallpox hospitals; for here, in numerous instances, it is only the unvaccinated individuals who have contracted the disease. While vaccination is undoubtedly efficacious in protecting against smallpox, Jenner was wrong in supposing that a vaccination in infancy afforded protection for more than a certain number of years thereafter. It has been noted in smallpox epidemics that whereas young unprotected subjects readily contract the disease,

those vaccinated as infants escape more or less till after the thirteenth to the fifteenth years. Revaccination is therefore necessary if immunity is to continue; and where this is done in any population, smallpox becomes a rare disease, and the mortality is practically nil. The whole question of the efficacy of vaccination was investigated in this country in 1896 by a Royal Commission, whose general conclusions were as follows: Vaccination diminishes the liability to attack by smallpox, and when the latter does occur, the disease is milder and less fatal. Protection against attack is greatest during nine or ten years after vaccination. It is still efficacious for a further period of five years, and possibly never wholly ceases. The power of vaccination to modify an attack outlasts its power wholly to ward it off. Revaccination restores protection, but this operation must be from time to time repeated. Vaccination is beneficial according to the thoroughness with which it is performed.

The Relationship of Smallpox (Variola) to Cowpox (Vaccinia).—This is a question regarding which great controversy has taken place; a subsidiary point has been the interrelationships within the group of animal diseases which includes cowpox, horsepox, sheep-pox, and cattle-plague. With reference to smallpox and cowpox the problem has been, Are they identical or not? There is no doubt that cowpox can be communicated to man, in whom it produces the eruption limited to the point of inoculation, and the slight general symptoms which vaccination with calf lymph has made familiar. Apparently against the view that cowpox is a modified smallpox are the facts that it never reproduces in man a general eruption, and that the local eruption is only infectious when matter from it is introduced into an abrasion. In the parallel condition in the guinea-pig, however, Camus has produced a general eruption by the intravenous injection of calf lymph. The loss of infectiveness by transmission through the body of a relatively insusceptible animal is a condition which is familiar in other diseases, and the uniformity of the type of the affection resulting from vaccination with calf lymph finds a parallel in hydrophobia, where, after passage through a series of monkeys, a virus of attenuated but constant virulence can be obtained. In considering the relationships of cowpox and smallpox, the immunity which the virus of calf lymph confers against human smallpox is an important though subsidiary point. It has been found that monkeys treated with vaccine lymph become after a few days immune against infection with variola. The significance of such an

observation is that it is questionable whether there are any well-authenticated instances of one disease having the capacity of conferring immunity against another. A question arising in this connection is what happens when inoculations of smallpox matter are made on cattle. Chauveau denies that in such circumstances cowpox is obtained. He, however, only experimented on adult cows. The transformation has been accomplished by many observers, including, in this country, Simpson, Klein, Hime, and Copeman. The general result of these experiments has been that if a series of calves is inoculated with variolous matter, in the first there may not be much local reaction, though redness and swelling appear at the point of inoculation, and some general symptoms manifest themselves. On squeezing some of the lymph from such lesion as occurs, and using it to continue the passages through other calves, after a very few transfers a local reaction indistinguishable from that caused by cowpox lymph generally takes place, and the animals are now found to be immune against the latter. Not only so, but on using for human vaccination the lymph from such variolated calves, results indistinguishable from those produced by vaccine lymph are obtained, and the transitory illness which follows, unlike that produced in man by inoculation with smallpox lymph, is no longer infectious. In fact, many of the strains of lymph in use in Germany at present have been derived thus from the variolation of calves. At present there is the strongest ground for holding not only that vaccinia confers immunity against variola, but that variola confers immunity against vaccinia. In the absence of proof based on the isolation of identical organisms from the two conditions we are at present justified in considering that vaccinia and variola are the same disease, and that the differences between them result from the relative susceptibilities of the two species of animals in which they occur naturally.

With regard to the relation of cowpox to horsepox, it is probable that they are the same disease. Some epidemics of the former have originated from the horse, but in other cases such a source has not been traced. Cattle-plague from the clinical standpoint, and also from that of pathological anatomy, resembles very closely human smallpox. Though each of the two diseases is extremely infectious to its appropriate animal, there is no record of cattle-plague giving rise to smallpox in man or *vice versa*. When matter from a cattle-plague pustule is inoculated in man, a pustule resembling a vaccine pustule occurs, and further, the individual is asserted to be now

immune to vaccination; but vaccination of cattle with cowpox lymph offers no protection against cattle-plague, though some have looked on the latter as merely a malignant cowpox. Sheep-pox also has many clinical and pathological analogies with human smallpox, and facts as to its relation to cowpox vaccination similar to those observed in cattle-plague have been reported. Smallpox, cowpox, cattle-plague, horsepox, and sheep-pox, in short, constitute an interesting group of analogous diseases, of the true relationships of which to one another we are, however, still ignorant.

The Virus of Smallpox and Vaccinia.—Burdon-Sanderson and others early pointed out that in the discharge of variolous and vaccine pustules—especially in the later stages—pyogenic organisms are present and ordinary skin saprophytes also occur. Klein and Copeman described a bacillus which was difficult to cultivate, but no organism has ever been isolated from the characteristic lesions which, on transference to animals, has been shown to produce specific effects. The adventitious bacteria present in lymph are usually removed or reduced in numbers by emulsifying it with glycerine before use. Calmette and Guerin removed these organisms by subjecting them to phagocytosis in the rabbit's peritoneum, and found in the bacterium-free lymph very minute granules, which, however, resisted attempts at cultivation. Such a material still produces vaccinia, and the same effect is obtained with lymph passed through a Berkefeld filter, so that the infective agent must be of great minuteness and is to be grouped with the filterable viruses. Noguchi has obtained results similar to those of the French observers by *passage* of the virus through the testicle in a series of rabbits.

Various observers have described structures in the epithelial cells in the neighbourhood of the smallpox or vaccine pustules, which they have interpreted as being protozoa. Thus Ruffer and Plimmer describe as occurring in clear vacuoles in the cells of the rete Malpighii at the edge of the pustule (in paraffin sections of vaccine and smallpox pustules carefully hardened in alcohol, and stained by the Ehrlich-Biondi mixture) small round bodies of about four times the size of a staphylococcus pyogenes, coloured red by the acid fuchsin, sometimes with a central part stained by the methyl-green. These are described as multiplying by simple division, and in the living condition exhibiting amœboid movement. Similar bodies have been described by Reed in the blood of smallpox patients and of vaccinated children and calves.

These are probably the bodies described by Guarnieri, and to

which considerable attention has been paid. They are from 1 to 8 μ in diameter, are round, oval, or sickle-shaped, and stain by ordinary nuclear dyes. They lie in the cells in spaces often near the nucleus, and are readily demonstrable in vaccine pustules and also in the experimental lesions which can be produced in the rabbit's cornea, the larger bodies being defined in the cells towards the centre of the lesion. These bodies have been looked on by many as protozoa, and Guarnieri himself stated that multiplication could be seen occurring in them in fresh lymph; but Ewing and also Prowazek brought forward strong evidence for the appearances being due to nuclear changes, though the latter observer considers them to be the effect of a specific reaction of epithelial cells against the variolous virus. Here, it may be said, Wasielewski has shown that they persist through 46 transfers on the cornea of the rabbit, and, further, no similar appearances have been found in other skin lesions. Prowazek examined material fixed in a hot mixture of two-thirds saturated perchloride of mercury and one-third 98 per cent. alcohol, washed in 40 per cent. iodine alcohol and stained in Grenacher's hæmatoxylin, and found bodies in the epithelial cells 1 to 4 μ in size, sharply contoured and having ragged edges as if made up of massed chromosomes. These were often broader at one end than at the other, and appearances have been seen which suggest longitudinal division. Prowazek also saw these "lymph-bodies," as he called them, in the lymph, and he inclined to the idea that they may be protozoa. Bonhoff and also Carini have described spirochætes as occurring in variolous lesions, but this has not been confirmed. Volpino states that in the epithelial cells in corneal infection in rabbits, minute motile bodies can be discerned which do not occur in other corneal inflammations. Future investigations must show what significance is to be attached to these various observations, but the existence of microscopic infective bodies in cells is, according to our view, not incompatible with their having also an ultramicroscopic stage (see p. 622).

The Nature of Vaccination.—The principle underlying the efficacy of vaccination as a prophylactic is no doubt the establishment of an active immunity against the causal organism, which is sufficiently lasting to protect the vaccinated individual for a considerable time. Although the virus of smallpox is unknown, several attempts have been made by indirect methods to establish the existence of reactions similar to those occurring in other immunisations. Thus, in cases of human smallpox and in animals intravenously injected with the vaccine lymph, it

is stated that the serum when mixed with vaccine lymph acquires the property of deviating complement, and evidence has also been obtained by Prowazek that the serum of monkeys infected subcutaneously contains substances of the nature of anti-bodies, for, when it is mixed with the lymph, the mixture is not capable of originating a vaccine pustule in children. Phenomena of hypersensitiveness on revaccination have also been described.

Considerable attention has been devoted to the study of the effects of corneal and cutaneous infection in the rabbit and monkey. Here it has been found that the infection of one cornea protects that eye against re-inoculation but not the other eye. Further, it is stated that while cutaneous vaccination causes the general skin surface after about ten days to become insusceptible, the cornea may still in the monkey be sensitive (this last fact is said not to be true for the rabbit). Again, intraperitoneal infection with lymph is said not to be followed by cutaneous immunity. Such facts have led some to suppose that smallpox is essentially a disease of the cutaneous tissues. In it we would have another example of local infection such as is found in tubercular leprosy, lupus, and certain other skin infections. Prowazek strongly held that in cutaneous vaccinal infection there is never a distribution of the virus throughout the organs; but this result has been disputed by other workers. He also stated that when the virus is injected intraperitoneally it is soon taken up by leucocytes and is not absorbed into the body fluids.

APPENDIX B.

HYDROPHOBIA.

SYNONYMS.—RABIES: *FRENCH*, LA RAGE: *GERMAN*, LYSSA, DIE HUNDWUTH, DIE TOLLWUTH.

Introductory.—Hydrophobia is an infectious disease which in nature occurs epidemically chiefly among the carnivora, especially in the dog and the wolf. Infection is carried by the bite of a rabid animal or by a wound or abrasion being licked by such. The disease can be transferred to other species, and when once started can be spread from individual to individual by the same paths of infection. Thus it occurs epidemically from time to time in cattle, sheep, pigs, horses, and deer, and can be communicated to man. Cases of infection from man to man by bite are recorded, but the saliva in man does not appear to be so infectious as in dogs. It is to be noted that the virus is apparently extremely potent, as cases of infection taking place through an unabraded mucous membrane by the licking of a rabid animal are on record, and the experimental applications of the virus to such surfaces as the mucous membrane of the nose or the conjunctiva is often followed by infection.

In Western Europe the disease is most frequently observed in the dog; but in Eastern Europe, especially in Russia, epidemics among wolves constitute a serious danger both to other animals and to man. All the manifestations of the disease point to a serious affection of the nervous system; but inasmuch as symptoms of excitement or of depression may predominate, it is customary to describe clinically two varieties of rabies—(1) rabies proper, or furious rabies (*la rage vraie, la rage furieuse; die rasende Wuth*); and (2) dumb madness or paralytic rabies (*la rage mue; die stille Wuth*). The disease, however, is essentially the same in both cases. In the dog the furious form is the more common. After a period of incubation of from three to six weeks, the first symptom noticed is a change in the animal's

aspect; it becomes restless, it snaps at anything which it touches, and tears up and swallows unwonted objects; it has a peculiar high-toned bark. Spasms of the throat muscles come on, especially in swallowing, and there is abundant secretion of saliva; its supposed special fear of water is, however, only part of the fear it has for swallowing generally. Gradually convulsions, paralysis, and coma come on; and death supervenes usually about five days after the appearance of symptoms. In the paralytic form, the early symptoms are the same, but paralysis appears sooner. The lower jaw of the animal drops, from implication of the elevator muscles, all the muscles of the body become more or less weakened, and death ensues without any very marked irritative symptoms.

In man the incubation period after infection varies from fifteen days to seven or eight months, or even longer, but is usually about forty days. When symptoms of rabies are about to appear, certain prodromata, such as pains in the wound and along the nerves of the limb in which the wound has been received, may be observed. To this succeeds a stage of nervous irritability, during which all the reflexes are augmented—the victim starting at the slightest sound, for example. There are spasms, especially of the muscles of deglutition and respiration, and cortical excitement evidenced by delirium may occur. On this follows a period in which all the reflexes are diminished, weakness and paralysis are observed, convulsions occur, and finally coma and death supervene. The duration of the acute illness is usually from four to eight days, and death invariably results. The existence of paralytic rabies in man has been denied by some, but it undoubtedly occurs. This is usually manifested by paralysis of the limb in which the infection has been received, and of the neighbouring parts; but while in such cases this is often the first symptom observed, during the whole of the illness the occurrence of widespread and progressive paralysis is the outstanding feature. In man there also occur cases where the cerebellum and also the sympathetic system seem to be specially affected.

The Pathology of Hydrophobia.—In hydrophobia as in tetanus, to which it bears more than a superficial resemblance, the appearances discoverable by an ordinary examination of the nervous system, to which all symptoms are naturally referred, are comparatively unimportant. On naked-eye examination, congestions, and, it may be, minute hæmorrhages are the only features noticeable. Microscopically, leucocytic exudation into the perivascular lymphatic spaces in the nerve centres has been observed,

and in the cells of the anterior cornua of the grey matter in the spinal cord, and also in the nuclei of the cranial nerves, various degenerations have been described. Round the nerve cells in the grey matter of the cord and medulla, Babès described accumulations of newly-formed cells, and Van Gehuchten observed a phagocytosis of the cells in the posterior root ganglia and also in the sympathetic ganglia. Both of these conditions were at one time thought to be specific of rabies, but this has been found not to be the case. In the white matter, especially in the posterior columns, swelling of the axis cylinders and breaking up of the myelin sheaths have been noted, and similar changes occur also in the spinal nerves, especially of the part of the body through which infection has come. In the nervous system also some have seen minute bodies which they have considered to be cocci, but there is no evidence that they are really of this nature. The changes in the other parts of the body are unimportant.

Experimental pathology confirms the view that the nervous system is the centre of the disease by finding in it a special concentration of what, from want of a more exact term, we must call the hydrophobic virus. Pasteur's first contribution to the subject was to show that the most certain method of infection was by inserting the infective matter beneath the dura mater. He found that in the case of any animal or man dead of the disease, injection by this method, of emulsions of any part of the central nervous system, of the cerebro-spinal fluid, or of the saliva, invariably gave rise to rabies, and also that the natural period of incubation was shortened. Further, the identity of the furious and paralytic forms was proved, as sometimes the one, sometimes the other, was produced, whatever form had been present in the original case. Inoculation into the anterior chamber of the eye is nearly as efficacious as subdural infection. Infection with the blood or solid organs of rabid animals does not reproduce the disease, though there is evidence that the poison exists in such glands as the pancreas and mamma. *Subcutaneous* infection with part of the nervous system of an animal dead of rabies may or may not give rise to the disease.

In consequence of the introduction of such reliable inoculation methods, further information has been acquired regarding the spread and distribution of the virus in the body. Gaining entrance by the infected wound, it early manifests its affinity for the nervous tissues. It reaches the central nervous system chiefly by spreading up the peripheral nerves. This can be

shown by inoculating an animal subcutaneously in one of its limbs with virulent material. If now the animal be killed before symptoms have manifested themselves, rabies can be produced by subdural inoculation from the nerves of the limb which was infected. Further, rabies can often be produced from such a case by subdural infection with the part of the spinal cord into which these nerves pass, while the other parts of the animal's nervous system do not give rise to the disease. This explains how the initial symptoms of the disease (pains along nerves, paralysis, etc.) so often appear in the affected part of the body, and it probably also explains the fact that bites in such richly nervous parts as the face and head are much more likely to be followed by hydrophobia than bites in other parts of the body. Again, injection into a peripheral nerve, such as the sciatic, is almost as certain a method of infection as injection into the subdural space, and gives rise to the same type of symptoms as injection into the corresponding limb. Intravenous injection of the virus, on the other hand, differs from the other modes of infection in that it more frequently gives rise to paralytic rabies. This fact Pasteur explained by supposing that the whole of the nervous system in such a case becomes simultaneously affected. In certain animals the virus seems to have an elective affinity for the salivary glands, as well as for the nervous system. Roux and Nocard found that the saliva of the dog became virulent three days before the first appearance of symptoms of the disease.

The Virus of Hydrophobia.—While a source of infection undoubtedly occurs in all cases of hydrophobia, and can usually be traced, all attempts to determine the actual morbific cause have been unsatisfactory. In this connection various organisms have been described as being associated with the disease, but none of these have been shown to possess the capacity of producing immunity against the ordinary hydrophobic virus.

The only definite information we possess regarding the causal organism of rabies is that in one stage of its life-history at any rate (see p. 622) it must be extremely small, as it can pass through the coarser Berkefeld filters and also sometimes through the coarser Chamberland filters. This is shown by the fact that if an emulsion of any infective material (*e.g.*, the brain) be thus filtered, the filtrate is also infective. Evidence that it is the organism itself which passes through is found in the fact that when an animal dies from infection with the filtrate, a small portion of its central nervous system will originate the disease in a fresh animal. Judging from our knowledge of similar

diseases, we would strongly suspect that it is actually present in a living condition in the central nervous system, the saliva, etc., which yield what we have called the hydrophobic virus, for by no mere toxin could the disease be transmitted through a series of animals, as we shall presently see can be done. A toxin may, however, be concerned in the production of the pathogenic effects. Remlinger found that death with paralytic symptoms followed the injection of filtered virus, but that the nervous system of the dead animals sometimes did not reproduce rabies. He explains this occurrence by supposing that under such circumstances the filtrate contained a toxin but not the actual infective agent. The resistance of the virus to external agents varies. Thus a nervous system containing it is virulent till destroyed by putrefaction; it can resist the prolonged application of a temperature of from $-10°$ to $-20°$ C., but, on the other hand, it is rendered non-virulent by one hour's exposure at 50° C. Again, its potency probably varies in nature according to the source. Thus, while the death-rate among persons bitten by mad dogs is about 16 per cent., the corresponding death-rate after the bites of wolves is 80 per cent. Here, however, it must be kept in view that, as the wolf is naturally the more savage animal, the number and extent of the bites, *i.e.*, the number of channels of entrance of the virus into the body and the total dose, are greater than in the case of persons bitten by dogs. As we shall see, alterations in the potency of the virus can certainly be effected by artificial means, such as drying, heating, and applying chemical agents. Various attempts have been made to make cultures from the hydrophobic virus, but convincing results have not been obtained.

In 1903, Negri described certain bodies as occurring in the nervous system in animals dying of rabies to which much attention has since been devoted, and regarding the significance of which opinion is still divided. As Negri's observations have been generally confirmed, and as it is probable that the occurrence of the bodies is specific to the disease, and that their recognition is of value for diagnosis, we shall describe the methods of their demonstration.

The method of Williams and Lowden is to take a piece of the brain tissue, to squeeze it between a slide and cover-glass, and, sliding off the latter, to make a smear which is then fixed in methyl-alcohol for five minutes and stained by Giemsa's stain (p. 113) for half an hour to three hours; the preparation is then washed in tap water for 2–3 minutes and dried. For rapid work, after fixation, equal parts of distilled water and stain are used instead of the more dilute mixture.

For sections the tissues are left in Zenker's fluid[1] for 3–4 hours, then placed in tap water for five minutes, 80 per cent. alcohol with enough iodine added to give it a port-wine colour for 24 hours; 95 per cent. alcohol and iodine, 24 hours; absolute alcohol, 4–6 hours; cleared with cedar oil and embedded in paraffin of melting-point 52° C.; sections should be 3 to 6 μ thick. For staining, Mallory's methylene-blue eosin is recommended; the steps are as follows: xylol; absolute alcohol; 95 per cent. alcohol and iodine, ¼ hour; 95 per cent. alcohol, ½ hour; absolute alcohol, ½ hour; eosin solution (5–10 per cent. aqueous solution), 20 minutes; rinse in tap water; Unna's polychrome methylene-blue solution diluted 1–4 with distilled water, 15 minutes; differentiation in 95 per cent. alcohol for 1–5 minutes (the preparation being kept in motion and its progress watched with a low power); rapid and careful dehydration and clearing.

Frothingham recommends a method of making "impression preparations" of the brain. The part (*e.g.*, hippocampus) is laid on a piece of wood whose porosity causes it to adhere; a clean slide is then lowered upon the tissue and slight pressure applied; on raising the slide a thin film of cells preserving their original arrangement is lifted off, and this can be fixed and stained like a smear, van Gieson's method being used by this author.

We have found that the bodies can be perfectly well demonstrated by fixing the brain in formalin, preparing paraffin sections and staining by Leishman's method.

The Negri bodies (Plate IV., Fig. 16)[2] vary much in size, measuring from ·5 to 25 μ. They are round, oval, or angular in outline. They are found in the protoplasm of the nerve cells and of their processes. When examined in unstained preparations, they are seen to have a sharply defined outline, and some of the features of the internal structure presently to be described can be noted. With regard to staining reactions, they are frankly eosinophil for certain combinations containing eosin, *e.g.*, alcoholic eosin-methylene-blue, Mann's eosin mixture, and, in certain circumstances, Leishman's stain. For the finer differentiation of the internal structure, Negri employed Giemsa's stain. With this stain and under high magnification the groundwork of the body is a pale blue; in it there appear certain round or oval, multiple or single formations, of varying size, stained pink, sometimes occupying nearly the whole of the body, sometimes being relatively small (*grosse Innenformationen*). In addition, both inside the larger formations and in the general protoplasm of the body are smaller red or violet-red granules, occurring

[1] Zenker's fluid is of the following composition: potassium bichromate ..... 2·5 gr., sodium sulphate 1 gr., perchloride of mercury 5 gr., glacial acetic acid 5 c.c., water to 100 c.c. Dissolve the perchloride of mercury and the bichromate of potassium in the water with the aid of heat and add the acetic acid.

[2] For the material from which this preparation was made we are indebted to Lt.-Col. W. F. Harvey, I.M.S.

singly or in clumps (*kleine Innenformationen*). With the eosin dyes named above, and magnifications of 800 to 1000, the smaller bodies appear a homogeneous reddish pink, and in the larger bodies the outlines of the larger internal formations can be recognised (see Plate). With Mallory's stain they present similar appearances with a bluish stippling of the protoplasm.

The Negri bodies have been found in practically 98 per cent. of cases of street rabies in dogs examined by many observers in different parts of the world. They are also found in natural rabies in other animals, and are usually present in human cases. Numerous control observations on other toxic conditions of the nervous system, especially where these are characterised by spasms, have been made, and although occasionally, *e.g.*, in tetanus, a somewhat similar appearance has been seen, at present the consensus of opinion is in favour of an experienced observer being able to recognise the Negri bodies as a specific appearance in nerve cells. The bodies occur in all parts of the nervous system, but are most common in the Purkinje cells of the cerebellum, and especially in the cells of the cornu Ammonis (hippocampus major). It is in the last situation, therefore, that they are generally looked for. They are apparently not so readily found, and at any rate the larger forms may be altogether absent, in animals dying from inoculation with the exalted fixed virus. Hitherto they have not been certainly found in the salivary glands or saliva of a rabid animal.

While there is a general tendency to recognise the Negri bodies as being specific to rabies, great difference of opinion exists as to their true nature and as to their possessing any etiological significance in the disease. Negri himself looks upon them as protozoa, and the organism has been named by Calkins *neuroryctes hydrophobiæ*. The chief arguments advanced in favour of this position have been the constancy of the occurrence of the bodies in the brains of animals suffering from the natural disease, and their peculiar structure which, such authorities as Golgi state, does not correspond to any cellular degeneration. Against their protozoal nature has been urged their absence from the virulent brains of animals dying from fixed virus, their non-discovery in the infected saliva, and the fact that the virus can pass through a coarse filter. These objections have been met with the argument that the smaller internal formations may be the infective agent in its essential form, and a modification of this view is that the Negri body is a cellular reaction against an invasion with these ultimate forms (see p. 622). The whole question must be looked upon as *sub judice*.

The Prophylactic Treatment of Hydrophobia.—Until the publication of Pasteur's researches in 1885, the only means adopted to prevent the development of hydrophobia in a person bitten by a rabid animal had consisted in the cauterisation of the wound. Such a procedure was undoubtedly not without effect. It has been shown that cauterisation within five minutes of the infliction of a rabic wound prevents the disease from developing, and that if done within half an hour it saves a proportion of the cases. After this time, cauterisation only lengthens the period of incubation; but, as we shall see presently, this is an extremely important effect.

The work of Pasteur, however, revolutionised the whole treatment of wounds inflicted by hydrophobic animals. Pasteur started with the idea that, since the period of incubation in the case of animals infected subdurally from the nervous systems of mad dogs is constant in the dog, the virus has been from time immemorial of constant strength. Such a virus, of what might be called natural strength, is usually referred to in his works as the virus of *la rage des rues*,[1] in the writings of German authors as the virus of *die Strasswuth*. Pasteur found on inoculating a monkey subdurally with such a virus, and then inoculating a second monkey from the first, and so on with a series of monkeys, that it gradually lost its virulence, as evidenced by lengthened periods of incubation on subdural inoculation of dogs, until it wholly lost the power of producing rabies in dogs, when introduced subcutaneously. When this point had been attained, its virulence was not diminished by further passage through the monkey. On the other hand, if the virus of *la rage des rues* were similarly passed through a series of rabbits or guinea-pigs, its virulence was increased till a constant strength (the *virus fixe*) was attained,—constancy of strength being indicated by the unvarying recurrence of paresis on the sixth day. Pasteur had thus at command three varieties of virus—that of natural strength, that which had been attenuated, and that which had been exalted. He further found that, commencing with the subcutaneous injection of a weak virus, and following this up with the injection of the stronger varieties, he could ultimately, in a very short time, immunise dogs against subdural infection with a virus which, under ordinary conditions, would

[1] While Pasteur's original statements regarding the constancy of the virulence of the street-virus were probably accurate for the street dogs of Paris, it has been found that if the general virulence of virus derived from animals in nature be studied, considerable variation occurs. It is now usual to apply the term street-virus to any virus derived from an animal becoming rabid under natural conditions of infection.

certainly have caused a fatal result. He also elucidated the fact that the exalted virus contained in the spinal cords of rabbits such as those referred to, could be attenuated so as no longer to produce rabies in dogs by subcutaneous injection. This was done by drying the cords in air over caustic potash (to absorb the moisture), the diminution of virulence being proportional to the length of time during which the cords were kept. Accordingly, by taking a series of such spinal cords kept for various periods of time, he was supplied with a series of vaccines of different strengths. Pasteur at once applied himself to find whether the comparatively long period of incubation in man could not be taken advantage of to "vaccinate" him against the disease before its gravest manifestation took place. The following is the record of the first case thus treated. The technique was to rub up in a little sterile bouillon a small piece of the cord used, and inject it under the skin by means of a hypodermic syringe. The first injection was made with a very attenuated virus, *i.e.*, a cord fourteen days old. In subsequent injections the strength of the virus was gradually increased, as shown in the table :—

July 7,	1885,	9 A.M.,	cord of June	23,	*i.e.*,	14	days old.

,, 15	,,	,,	,,	13	,,	2	,,
,, 16	,,	,,	,,	15	,,	1	day old.

The patient never manifested the slightest symptom of hydrophobia. Other similarly favourable results followed; and this prophylactic treatment of the disease quickly gained the confidence of the scientific world, which it still retains.

An important modification in the method which further experience led Pasteur to make was in the treatment of serious cases, such as multiple bites from wolves, extensive bites about the head, especially in children, cases which come under treatment at a late period of the incubation stage, and cases where the wounds have not cicatrised. In such cases the stages of the treatment are condensed. Thus on the first day, say at 11 A.M. and 4 P.M. and 9 P.M., cords of 12, 10, and 8 days respectively are used; on the second day, cords of 6, 4, and 2 days; on the third day, cords of 1 day; on the fourth day, cords of 8, 6, and 4 days; on the fifth, cords of 3 and 2 days; on the sixth, cords of 1 day; and so on for ten days. In each case the average dose is about 2 c.c. of the emulsion.

The details of the prophylactic treatment with regard to dosage and virulence of material used vary in different Pasteur institutes. The most important modification which has within recent times taken place is the substitution by Högyes of increasing concentrations of a fairly fresh virulent rabbit's cord for emulsions of cords subjected to decreasing periods of drying. Equally good results apparently are obtained by this method, and it is stated that in cases so treated certain symptoms sometimes following the ordinary treatment, the gravest of which may be the occurrence of temporary paralyses, are not so frequently observed. This, according to Harvey and M'Kendrick, who have studied the subject very fully, may be due to the fact that a smaller amount of nerve tissue is injected under the Högyes system.

The success of the treatment has been very marked. The statistics of the cases treated in Paris are published annually in the *Annales de l'Institut Pasteur*. The ordinary mortality is probably 16 per cent. of all persons bitten. During the ten years 1886–95, 17,337 cases were treated, with a mortality of ·48 per cent., and recent statistics show even more favourable results. It has been alleged that many people are treated who have been bitten by dogs that were not mad. This, however, is not more true of the cases treated by Pasteur's method than it was of those on which the ordinary mortality of 16 per cent. was based, and care is taken in making up the statistics to distinguish the cases into three classes. Class A includes only persons bitten by dogs proved to have had rabies, by inoculation in healthy animals of parts of the central nervous system of the diseased animal. Class B includes those bitten by dogs that a competent veterinary surgeon has pronounced to be mad. Class C includes all other cases. During 1895, 122 cases belonging to Class A were treated, with no deaths; 940 belonging to Class B, with two deaths; and 449 belonging to Class C, with no deaths. Besides the Institute in Paris, similar institutions exist in other parts of France, in Italy, and especially in Russia, as well as in other parts of the world; and in these similar success has been experienced. It may be now taken as established, that a very grave responsibility rests on those concerned, if a person bitten by a mad animal is not subjected to the Pasteur treatment. Sometimes during or after treatment there appear slight paralytic symptoms with obstinate constipation and it may be retention of urine, but these usually pass off within a few weeks and leave behind no ill-effects.

The principles underlying the prophylactic treatment of rabies raise questions of the highest interest from the standpoint of immunity. The prime fact is, as has been stated, the taking advantage of the long period of incubation of the disease in man to neutralise an infection which may be supposed to be gradually gathering force. We have here again to deal with an example of the reinforcement of the natural powers of resistance of the body in order to enable it to cope with a local pathological

change, the locus in this case being the nervous system. We are thus unable at present to give a rational explanation of the efficacy of the treatment, but again attention may be directed to the bearing which the development of hypersensitiveness may have to the occurrence of the phenomena of infective disease, and Harvey and M'Kendrick draw attention to the fact that some of the concurrent symptoms associated with the treatment closely resemble anaphylactic phenomena.

Antirabic Serum.—In the early part of the nineteenth century an Italian physician, Valli, showed that immunity against rabies could be conferred by administering through the stomach progressively increasing doses of hydrophobic virus. Following up this observation, Tizzoni and Centanni have attenuated rabic virus by submitting it to peptic digestion, and have immunised animals by injecting gradually increasing strengths of such virus. This method is usually referred to as the Italian method of immunisation. The latter workers showed from this that the serum of animals thus immunised could give rise to passive immunity in other animals; and further, that if injected into animals from seven to fourteen days after infection with the virus, it prevented the latter from producing its fatal effects, even when symptoms had begun to manifest themselves. They further succeeded in producing in the sheep and the dog an immunity equal to from 1–25,000 to 1–50,000 (*vide* p. 564), and they recommended the use, in severe cases, of the serum of such animals in addition to the treatment of the patient by the Pasteur method. Marie obtained a similar serum by subcutaneous injection of the sheep with *virus fixe*. The use of this serum to supplement the ordinary Pasteur treatment has been found beneficial in severe human infections, and in ordinary cases it enables the prophylactic injections of the virus to be condensed. The method is now part of the routine in many Pasteur Institutes. It probably prevents some of the purely toxic effects of the virus in human cases.

Methods.—(1) *Diagnosis.*—The work on the specificity of the Negri bodies for rabies has led to a modification in the procedure to be adopted. Formerly it was advisable if possible to keep an animal suspected of rabies alive for the observation of symptoms. While the clinical history of the animal ought to be carefully obtained, greater information will be obtained by examination of its hippocampus. The animal should therefore be killed and the brain removed after reflecting the scalp and cutting through the calvarium with a sharp chisel. The brain is laid down, vertex uppermost, and the upper parts of one hemisphere are removed in thin horizontal slices till the anterior part of the lateral ventricle is reached. The roof of the ventricle is then cut away with a probe-pointed

bistoury, and the hippocampus will be recognised as the laterally arched ridge which forms the floor of the ventricle. This may be transversely incised and parts removed for the making of smears and sections (p. 615).

In addition to microscopic examination, a small piece of the medulla or cord of the suspected animal must be taken, with all aseptic precautions, rubbed up in a little sterile ·75 per cent. sodium chloride solution, and injected by means of a syringe beneath the dura mater of a rabbit, the latter having been trephined over the cerebrum by means of the small trephine which is made for the purpose. In rabies in the rabbit, symptoms of paresis usually occur in from six to twenty-three days and death in fifteen to twenty-five days. When the material for inoculation has to be sent any distance, this is best effected by packing the head of the animal in ice. The virulence of organs is not lost, however, if they are simply placed in glycerin in well-stoppered bottles.

(2) *Treatment.*—Every wound inflicted by a rabid animal ought to be cauterised with the actual cautery as soon as possible. By such treatment the incubation period will at any rate be lengthened, and therefore there will be better opportunity for the Pasteur inoculation method being efficacious. The person ought then to be sent to the nearest Pasteur Institute for treatment. It is of great importance that in such a case the nervous system of the animal should also be sent, in order that the diagnosis may be certainly verified.

Addendum to Appendices A and B.

The scientific investigation of smallpox and rabies has shown, on the one hand, that it is impossible to associate the conditions with organisms belonging to any well-recognised group. On the other hand, much controversy has in each case been aroused regarding the interpretation to be put on peculiar changes seen in certain tissue cells. The situation is further complicated by the fact that in both diseases the causal agent can pass through a coarse earthenware filter and must therefore be extremely minute. Similar changes in cells and similar facts regarding the minuteness of the causal agents have raised like difficulties in other diseases, such as trachoma and molluscum contagiosum in man, foot-and-mouth disease in cattle, and in the diphtheria and epithelioma contagiosum of birds; by many, measles and scarlet fever are included in this group. In all the cellular changes described in these conditions, a common feature is the presence in the protoplasm of small chromatic granules often in groups. In recent years these have acquired new importance from the fact that Prowazek, using the highest microscopic powers, observed similar bodies occurring in infective exudates and of sufficient minuteness to pass through a coarse filter. Appearances have been seen in these particles which suggest multiplication. This takes place not by a simple fission as in the bacteria, but by the particle assuming a dumb-bell shape,

the two elements of which gradually recede from each other until the fine thread connecting them snaps. This special behaviour in division, taken along with the failure of attempts at culture, has caused them to be put in a special group—the *chlamydozoa*. The view held is that they are the actual infective agents. On gaining admission to the cells for which they have an affinity, they originate a reaction whereby the protoplasm forms round them a sheath or mantle (χλαμύς), which accounts for the gross appearances seen in, *e.g.*, the epithelial cells in smallpox and in those of the cornu Ammonis in rabies. In these the parasite multiplies to produce such appearances as the initial corpuscles of the Guarnieri bodies and the *kleine Innen-inklusionen* of Negri. It is obvious that at present no definite position can be taken up regarding the cogency of these views.

APPENDIX C.

MALARIAL FEVERS.

It has now been conclusively proved that the malarial fevers are protozoal infections, there being several species of parasite. These belong to the hæmosporidia (a sub-class of the sporozoa), which are blood parasites, infecting the red corpuscles of mammals, reptiles, and birds. The parasite was formerly known as the *hæmatozoon* or *plasmodium malariæ*; the term *hæmamœba* is, however, now generally employed. It was first observed by Laveran in 1880, and his discovery received confirmation from the independent researches of Marchiafava and Celli, and later from the researches of many others in various parts of the world. Golgi supplied valuable additional information, especially in relation to the sporulation of the organism and the varieties in different types of malarial fever. In this country valuable work on the subject was done by Manson, and to him specially belongs the credit of regarding the exflagellation of the organism as a preparation for an extra-corporeal phase of existence. By induction he arrived at the belief that the cycle of existence outside the human body probably took place in the mosquito. It was specially in order to discover, if possible, the parasite in this insect, that Ross commenced his long series of observations, which were ultimately crowned with success. After patient and persistent search, he found rounded pigmented bodies in the wall of the stomach of a dapple-winged mosquito (a species of Anopheles) which had been fed on the blood of a malarial patient. The pigment in these bodies was exactly similar to that in the malarial parasite, and he excluded the possibility of their representing anything else than a stage in the life-cycle of the organism. He confirmed this discovery and obtained corresponding results in the case of the proteosoma infection of birds, where the parasite is closely related to that of malaria. In birds affected with this organism, he was able to trace all stages of its development, from the time it entered

the stomach along with the blood, till the time when it settled in a special form in the salivary glands of the insect. Ross's results were published in 1898. Exactly corresponding stages were afterwards found in the case of the different species of the human parasite, by Grassi, Bignami, and Bastianelli; and these with other Italian observers also supplied important information regarding the transmission of the disease by infected mosquitoes. Abundant additional observations, with confirmatory results, were supplied by Koch, Daniels, Christophers, Stephens, and others. Whefever malaria has been studied the result has been the same. Lastly, we may mention the striking experiment carried out by Manson by means of mosquitoes fed on the blood of patients in Italy suffering from mild tertian fever. The insects, after being thus fed, were taken to London and allowed to bite the human subject, Manson's son, Dr. P. Thurburn Manson, offering himself for the purpose. The result was that infection occurred; the parasites appeared in the blood, and were associated with an attack of tertian fever. Ross's discovery has not only been a means of elucidating the mode of infection, but, as will be shown below, has also supplied the means of successfully combating the disease.

From the zoological point of view the mosquito is regarded as the definitive host of the parasite, the human subject as the intermediate host. But in describing the life-history, it will be convenient to consider, first, the cycle in the human body, and, secondly, that in the mosquito. We shall first give a general account of the life-history and then describe the features of the different species.

The Asexual Cycle in the Human Subject—Schizogony.—With regard to this cycle (Plate V., Fig. 21 *a–i*), it may be stated that the parasite is conveyed by the bite of the mosquito in the form of a small filamentous cell—*sporozoite* or *exotospore*, which penetrates a red corpuscle and becomes a small amœboid organism or amœbula. There is then a regularly repeated asexual cycle of the parasite in the blood, the length of which cycle determines the type of the fever. During this cycle there is a growth of the amœbulæ or trophozoites within the red corpuscles up to their complete development; schizogony (formerly called sporulation) then occurs. The onset of the febrile attack corresponds with the stage of schizogony and the setting free of the merozoites or enhæmospores, *i.e.*, with the production of a fresh brood of parasites. These soon become attached to, and penetrate into, the interior of the red corpuscles, becoming intra-corpuscular trophozoites; the cycle is thus com-

pleted. The parasites are most numerous in the blood during the development of the pyrexia, and, further, they are also much more abundant in the internal organs than in the peripheral blood; in the malignant type, for example, the process of schizogony is practically confined to the former.

In addition to these forms which are part of the ordinary asexual cycle, there are derived from the amœbulæ other forms, which are called *gametocytes*, or sexual cells. These remain unaltered during successive attacks of pyrexia, and undergo no further change until the blood is removed from the human body. In the simple tertian and quartan fevers (*vide infra*) the gametocytes are rounded in form, resembling somewhat in appearance the fully developed amœbulæ before schizogony, whereas in the malignant type they have a characteristic crescent-like or sausage-shaped form; hence they are often spoken of as "crescentic bodies" (Plate V., Fig. 22, *f*, *g*).

The various forms of the parasite seen in the human blood may now be described more in detail.

1. *The Merozoites* (*Enhæmospores*, Lankester) are the youngest and smallest forms resulting from the segmentation of the adult amœbula or schizont. They are of round or oval shape and of small size, usually not exceeding 2 μ in diameter; the size, however, varies somewhat in the different types of fever. A nucleus and peripheral protoplasm can be distinguished (Fig. 180). The former appears as a small rounded body which usually remains unstained, but contains a minute mass of chromatin which stains a deep red with the Romanowsky method, the peripheral protoplasm being coloured fairly deeply with methylene-blue. The merozoites show little or no amœboid movement; at first free in the plasma, they soon attack the red corpuscles, where they become the intra-corpuscular amœbulæ. If the blood, say in a mild tertian case, be examined in the early stages of pyrexia, one often finds at the same time schizonts, free merozoites, and the young amœbulæ within the red corpuscles.

2. *Intra-corpuscular Amœbulæ or Trophozoites.*—These include the parasites which have attacked the red corpuscles; they are at first situated on the surface of the latter, but afterwards penetrate their substance. They usually occur singly in the red corpuscles, but sometimes two or more may be present together. As seen in fresh blood, the youngest or smallest forms are minute colourless specks, of about the same size as the merozoites; they exhibit more or less active amœboid movement, showing marked variations in shape. The amount and character of the amœboid

movement varies somewhat in different types of fever. As they increase in size, pigment appears in their interior as minute dark brown or black specks, and gradually becomes more abundant (Figs. 175–177; Plate V., Fig. 21 *c*, *d*, *e*, Fig. 22 *e*). This pigment is elaborated from the hæmoglobin of the red corpuscles, the parasite growing at the expense of the latter. The red corpuscles thus invaded may remain unaltered in appearance (quartan fever), may become swollen and pale (tertian fever), or somewhat shrivelled and of darker tint (malignant fever). In stained specimens a nucleus may be seen in the parasite as a pale spot containing chromatin which may be arranged as a single concentrated mass or as several separated granules, the chromatin being coloured a deep red by the Romanowsky method. The protoplasm of the parasite, which is coloured of varying depth of tint with methylene-blue, shows great variation in configuration (Fig. 177). The young parasites not infrequently present a "ring-form," a portion of the red corpuscle being often enclosed by the parasite. These ring-forms are met with in all the varieties of the parasite, but they are especially common in the case of the malignant parasite, where they are of smaller size and of more symmetrical form than in the others (Fig. 181).

Within the red corpuscles the parasites gradually increase in size till the full adult form is reached (Fig. 178). In this stage the parasite loses its amœboid movement more or less completely, has a somewhat rounded form, and contains a considerable amount of pigment. In the malignant form it only occupies a fraction of the red corpuscle. The adult parasites may then undergo schizogony, but not all of them do so; some become degenerated and ultimately break down.

3. *Schizonts.*—In the process of schizogony the nuclear outline becomes lost, and the chromatin becomes divided into a number of small granules which are scattered through the protoplasm; the latter then undergoes corresponding segmentation and the small merozoites or enhæmospores result. The pigment during the process becomes aggregated in the centre and is surrounded by a small quantity of residuary protoplasm. (Schaudinn has found in the case of the tertian parasite that schizogony begins by a sort of primitive mitosis, which is then followed by simple multiple fission.) The merozoites are of rounded or oval shape, as above described, and are set free by the rupture of the envelope of the red corpuscles. The pigment also becomes free and may be taken up by leucocytes. The number and arrangement of the merozoites within the

Figs. 183–186 illustrate the changes in form undergone by the crescents outside the body. In the interior of the spherical form in Fig. 185 evidence of the flagella can be seen. Fig. 186. A male gametocyte which has undergone exflagellation, showing the thread-like microgametes or spermatozoa attached at the periphery. ×1000. (The figures in this plate are from preparations kindly lent by Sir Patrick Manson.)

schizont vary in the different types. In the quartan there are 6–12, and the segmentation is in a radiate manner, giving rise to the characteristic daisy-head appearance; in the tertian they number 15–20 or more, and have a somewhat rosette-like arrangement (Fig. 179); in the malignant there are usually 6–20 or more merozoites of small size and somewhat irregularly arranged.

Gametocytes.—As stated above, these are sexual cells which are formed from certain of the amœbulæ, and which undergo no further development in the human subject. In the mild tertian and quartan fevers they are rounded and resemble somewhat the largest amœbulæ. The female cells, *macrogametocytes*, are rounded and of large size, measuring up to 16 μ in diameter; they contain coarse grains of pigment, and the protoplasm stains somewhat deeply with methylene-blue. The male cells, *microgametocytes*, are smaller, and the protoplasm stains faintly; the nucleus, generally in the centre, is rich in chromatin. In the malignant fevers the gametocytes have the special crescentic or sausage-shaped form mentioned above. They measure 8 to 9 μ in length, and occasionally a fine curved line is seen joining the extremities on the concave aspect, which represents the envelope of the red corpuscle (Fig. 182). They are colourless and transparent, and are enclosed by a distinct membrane; in the central part there is a collection of pigment and granules of chromatin. The male crescents (Plate V., Fig. 22 *f*) can be distinguished from the female (ibid., *g*.) by their appearance; the former are somewhat sausage-shaped, the pigment is less dark and more scattered through the cell, and there are several granules of chromatin; the latter have more pointed ends and their substance stains more deeply with the blue, the pigment is dark and concentrated, often in a small ring, and there are one or two masses of chromatin in the centre of the crescent. According to the Italian observers, the early forms of the crescents are somewhat fusiform in shape and are produced in the bone-marrow. The fully developed crescents do not appear in the blood till several days after the onset of the fever, and they may be found a considerable time after the disappearance of the pyrexial attacks. They are also little, if at all, influenced by the administration of quinine. Ross and Thomson have enumerated directly (p. 640) the malarial parasites in the blood at different stages of the disease, and have found that a certain relationship exists between the asexual and the sexual forms, a rise in the number of the former being followed eight to ten days later by a rise in the number of

the latter; they accordingly consider that this is probably the period necessary for the development of the sexual forms. They also consider that the long persistence of crescents in the blood after the fever has ceased, is due not to the long survival of individual crescents, but to their being constantly replenished from asexual forms which persist in the blood and pass through the ordinary process of schizogony, fever only occurring when the number of asexual forms reaches some hundreds per cubic millimetre.

It is well known that after a patient has apparently recovered from malarial fever a relapse may take place without fresh infection occurring, sometimes several years afterward, and Schaudinn has published interesting observations bearing on this point. He has found, and his observations on this point have been confirmed, that the macrogametocyte of tertian fever may by a process of parthenogenesis give rise to merozoites, which in their turn infect the red corpuscles and start the cycle again. As described and figured by him, the chromatin of the macrogametocyte divides first into two portions, one of which is smaller and stains more deeply than the other. This more deeply staining portion then divides, and the protoplasm becomes segmented as in ordinary schizogony, and a young brood of parasites results. The more faintly staining chromatin along with part of the protoplasm breaks up and disappears. The observations of Ross and Thomson, just referred to, have however led them to the conclusion that the occurrence of relapses does not depend on resistant forms and parthenogenesis, but on the survival of asexual forms in small numbers, which pass through the ordinary cycle and only produce fever when they again become sufficiently numerous.

The Sexual Cycle in the Mosquito—Sporogony.—As already explained, this starts from the gametocytes. After the blood is shed, or after it is swallowed by the mosquito, two important phenomena occur, namely, (*a*) the full development of the sexual cells or gametocytes, and (*b*) the impregnation of the female cell (Plate V., Fig. 21 *m–q*). If the blood from a case of malignant infection be examined in a moist chamber, preferably on a warm stage, under the microscope, both male and female gametocytes may be seen to become oval and afterwards rounded in shape (Figs. 183–185). Thereafter, in the case of the male cell, a vibratile or dancing movement of the pigment granules can be seen in the interior, and soon several flagella-like structures shoot out from the periphery (Fig. 186). They are of considerable length but of great fineness, and often show a somewhat bulbous

extremity. By the Romanowsky method they have been found to contain a delicate core of chromatin, which is covered by protoplasm. They represent the male cells proper, that is, they are sperm-cells or spermatozoa; they are also known as *microgametes*. They become detached from the sphere and move away in the surrounding fluid. In the female cell, which has also assumed the rounded form, maturation takes place by the giving off of part of the nuclear chromatin, this process corresponding to the formation of a polar body. Impregnation occurs by the entrance of a microgamete, the chromatin of the two cells afterwards becoming fused. Similar changes occur in the gametocytes of the mild fevers, but, as has been said, the cells are rounded from the first. Impregnation was first observed by M'Callum in the case of halteridium, and he found that the female cell afterwards acquired the power of independent movement or became a "travelling vermicule." He also observed the impregnation of the malignant parasite. The fertilised female cell is now generally spoken of as a *zygote* or *oökinete*.

It has been established that the phenomena just described occur within the stomach of the mosquito, and that the fertilised cell or zygote penetrates the stomach wall and settles between the muscle fibres; on the second day after the mosquito has ingested the infected blood, small rounded cells about 6 to 8 μ in diameter, and containing clumps of pigment, may be found in this position. (It was, in fact, the character of the pigment which led Ross to believe that he had before him a stage in the development of the malarial parasite.) A distinct membrane called a *sporocyst* forms around the zygote, and on subsequent days a great increase in size takes place, the cysts coming to project from the surface of the stomach into the body cavity. The zygote divides into a number of cells called *blastophores* or *sporoblasts*, and these again divide and form a large number of filiform cells which have a radiate arrangement; these were called by Ross "germinal rods," but are now usually known as *sporozoites* or *exotospores* (in contradistinction to the enhæmospores of the human cycle). The full development (*sporogony*) within the sporocyst occupies, in the case of proteosoma, about seven days, in the case of the malarial parasites a little longer. When fully developed the cyst measures about 60 μ in diameter, and appears packed with sporozoites. It then bursts, and the latter are set free in the body cavity. A large number settle within the large veneno-salivary gland of the insect, and are thus in a position to be injected along with its secretion into the human subject. The sporozoites enter red corpuscles and become

trophozoites, as above described. Daniels found that, in the case of the malignant parasite, an interval of twelve days at least intervened between the time of feeding the mosquito and the appearance of the sporozoites in the gland.

It will thus be seen that in the human subject the parasite passes through an indefinite number of regularly recurring asexual cycles, with the giving off of collateral sexual cells, and that in the mosquito there is one cycle which may be said to start with the impregnation of the female gamete.

Varieties of the Malarial Parasites.—The view propounded by Laveran was that there is only one species of malarial parasite, which is polymorphous, and presents slight differences in structural character in the different types of fever. It may, however, now be accepted that there are at least three distinct species which infect the human subject. Practically all are agreed as to a division into two groups, one of which embraces the parasites of the milder fevers—"winter-spring" fevers of Italian writers—there being in this group two distinct species, for the quartan and tertian types respectively; whilst the other includes the parasites of the severer forms—"æstivo-autumnal" fevers, malignant or pernicious fevers of the tropics, or irregularly remittent fevers. There is still doubt as to whether there are more than one species in this latter group. Formerly Italian writers distinguished (1) a quotidian; (2) a non-pigmented quotidian; and (3) a malignant tertian parasite, though the morphological differences described were slight. Further observations have, however, thrown doubt on this distinction, and the evidence rather goes to show that there is a single species. Opinion also varies as to the cycle of this parasite; according to some observers it is twenty-four hours, according to others forty-eight hours; though there is more evidence in support of the latter view, and the term "malignant tertian" is frequently used. The fever is often of an irregular type and multiple infection is probably common. Although the question cannot be considered as finally settled, we shall speak of three species of human parasites. The zoological position may be shown by the following scheme, generally followed by English writers, the terminology being chiefly that of Grassi and Feletti:—

Family: HÆMAMŒBIDÆ (Wasielewski).

Genus I. Hæmamœba. The mature gametocytes resemble in form the schizonts before segmentation has occurred.

Species 1. *Hæmamœba danilewski* or *halteridium*.
Parasite of pigeons, crows, etc.

Species 2. *Hæmamœba relicta* or *proteosoma*.
Parasite of sparrows, larks, etc.

Species 3. *Hæmamœba malariæ* (*Plasmodium malariæ*).
Parasite of quartan fever of man.

Species 4. *Hæmamœba vivax* (*Plasmodium vivax*).
Parasite of tertian fever of man.

Genus II. Hæmomonas. The gametocytes have a special crescentic form.

Species: *Hæmomenas præcox* (*Plasmodium falciparum*).
Parasite of malignant, sub-tertian, or æstivo-autumnal fever of man.

In addition, there are other species belonging to the same family of blood parasites, which infect monkeys, bats, frogs, lizards, etc., especially in malarial regions.

We shall now give the chief distinctive characters of the three human parasites:—

1. *Parasite of Quartan Fever.*—The cycle of development in man is seventy-two hours, and produces pyrexia every third day; double or triple infection may, however, occur. In fresh specimens of blood the outline is more distinct than that of the tertian parasite, and amœboid movement is less marked. Only the smaller forms show movement, and this is not of active character. The infected red corpuscles do not become altered in size or appearance, and the pigment within the parasite is in the form of coarse granules, of dark brown or almost black colour. The fully developed schizont has a "daisy-head" appearance, dividing by regular radial segmentation into from six to twelve merozoites, which, on becoming free, are rounded in form.

2. *The Parasite of Mild Tertian Fever.*—The cycle of development is completed in forty-eight hours, though a quotidian type of fever may be produced by double infection. The amœbulæ have a less refractile margin than in the quartan type, and are thus less easily distinguished in the fresh blood; the amœboid movements are, however, much more active, while longer and more slender processes are given off. The infected corpuscles become swollen and pale, and may show deeply stained points by the Romanowsky method—"Schüffner's dots." The pigment within the parasite is fine and of yellowish-brown tint. The mature schizont is rather larger than in the quartan, has a rosette appearance, and gives rise to from fifteen to twenty merozoites, though sometimes even more occur; these have a somewhat oval shape.

In both the quartan and tertian fevers all the stages of

development can be readily observed in the peripheral blood. The gametocytes have a rounded form as described above.

3. *The Parasite of Malignant or Sub-tertian Fever or Tropical Malaria.*—The cycle in the human subject probably occupies forty-eight hours, though this cannot be definitely stated to be always the case (*vide supra*). The amœbulæ in the red corpuscles are of small size, and their amœboid movements are very active; they often, however, pass into the quiescent ring form (Fig. 182). The pigment granules, even in the larger forms, are few in number and very fine; the infected red corpuscles have a tendency to shrivel and assume a deeper or coppery tint, sometimes they are swollen and decolorised. The fully developed schizont usually occupies less than half the red corpuscle, and gives rise to from six to twenty or more merozoites, somewhat irregularly arranged and of minute size. Schizogony takes place almost exclusively in the internal organs, spleen, etc., so that, as a rule, no schizonts can be found in the blood taken in the usual way. The proportion of red corpuscles infected by the amœbulæ is also much larger in the internal organs. The gametocytes have the crescentic form, as already described.

Cases of infection with the malignant parasite sometimes assume a pernicious character, and then the number of organisms in the interior of the body may be enormous. In certain fatal cases with coma the cerebral capillaries appear to be almost filled with them, many parasites being in process of schizogony; and in so-called algid cases, characterised by great collapse, a similar condition has been found in the capillaries of the omentum and intestines. The process of blood destruction, present in all malarial fevers, reaches its maximum in the malignant class, and the brown or black pigment elaborated by the parasites—in part after being taken up by leucocytes, chiefly of the mononuclear class—becomes deposited in various organs, spleen, liver, brain, etc., especially in the endothelium of vessels and the perivascular lymphatics. In the severer forms also brownish yellow pigment is apparently derived from liberated hæmoglobin, and accumulates in various parts, especially in the liver cells; most of this latter gives the reaction of hæmosiderin.

Cultivation.—Bass and Johns succeeded in obtaining growths of the parasites of tertian and malignant fevers outside the body. The first cultures were obtained in defibrinated blood from malarial patients, to which was added 1 per cent. of a 50 per cent. solution of dextrose in water. Growth of the parasites took place within the red corpuscles, but only under anaerobic conditions, and there must be a layer of serum at least half an

inch in depth above the sedimented corpuscles. Under such circumstances, the parasites underwent enlargement and afterwards passed through the stage of schizogony. The merozoites after becoming free are destroyed by leucocytes, but if measures are taken to prevent the presence of these, other generations of growth may be obtained in similarly prepared tubes of blood with sufficient serum. The parasites flourish only in the superficial layers of the sedimented corpuscles, and the most suitable temperature is 40–41° C. These results have been confirmed by Thomson and M'Lellan.

General Considerations.—The development of the malarial parasites in the mosquito and infection of the human subject through the bites of this insect, have, by the work of Ross and others, as detailed above, become established scientific facts. These facts, moreover, point to certain definite methods of prevention of infection, which have to a certain extent already been practically tested. The extensive observations carried out go to show that all the mosquitoes which act as hosts of the parasite belong to the genus *anopheles*; of these there are a large number of species, and in at least eight or nine the parasite has been found. Some of these anopheles occur in England, especially in regions where malaria formerly prevailed. The opportunity for infection from cases of malaria returning from the tropics to this country thus exists, and such infection has occurred. The breeding-places of the insects are chiefly, though not exclusively, in stagnant pools and other collections of standing water, and accordingly the removal, where practicable, by drainage of such collections in the vicinity of centres of population, the covering in of wells, etc., and the killing of the larvæ by petroleum sprinkled on the water, have constituted the most important measures in localised areas. This procedure has been carried out in various places, for example, in Freetown and Ismailia, with marked success. On the other hand, where there are large populous areas, as in India, it has been found almost impracticable to carry out these measures with any success. Another measure is the protection against mosquito bites by netting, it being fortunately the habit of the anopheles rarely to become active before sundown. The experiments of Sambon and Low in the Campagna proved that individuals using these means of protection may live in a highly malarial district without becoming infected. The administration of quinine to persons living in highly malarial regions, in order to *prevent* as well as to treat infection, has also been recommended and carried out, and there appears to be general agreement that in

India the properly controlled administration of quinine must, in the meantime at least, be the chief means of combating the disease. In the tropics the natives in large proportion suffer from malarial infection, and one would accordingly expect that infection of the mosquitoes in the neighbourhood of native settlements would be common. This has been found to be actually the case, and it has accordingly been suggested that the dwellings of whites should as far as possible be at some distance from the native centres of population.

So far as is known, none of the lower animals have been found to take the place of man as intermediate host to the parasites of malaria, but the possibility of such being the case cannot be as yet definitely excluded. On the death of infected mosquitoes the sporozoites will become set free, and therefore theoretically there is a possibility that they may enter the human subject by inhalation or by some other means. We have no facts, however, to show that this really occurs, and the evidence already obtained establishes the bites of mosquitoes as the most important if not the only mode of infection.

It may also be mentioned as a scientific fact of some interest, though not bearing on the natural modes of infection, that the disease can also be communicated from one person to another by injecting the blood containing the parasites. Several experiments of this kind have been performed (usually about $\frac{1}{2}$ to 1 c.c. of blood has been used), and the result is more certain in intravenous than in subcutaneous injection. In such cases there is an incubation period, usually of from seven to fourteen days, after which the fever occurs; the same type of fever is reproduced as was present in the patient from whom the blood was taken.

The Pathology of Malaria.—While much work has been done on the malarial parasite, relatively less attention has been directed to the processes by which it produces its pathogenic effects. It may be said that the organisms are not always equally prevalent in the circulating blood, and at certain stages tend to be confined in the internal organs. Some of the pathogenic effects are probably associated with particular stages in the life-cycle. Thus the pyrexia occurs when the stage of schizogony is actively in progress. No opinion can be stated, however, as to the cause of the fever,—whether it is due to a toxic process or to general disturbance of metabolism. We can better explain the anæmia which is so pronounced in cases where the disease is of long standing, and which is due to the actual destruction of red blood corpuscles. The parasite in its sojourn

in these cells absorbs their pigment and thus destroys their function; this is further evidenced by the activity displayed by the red marrow in its attempts to make good the loss sustained by the blood. One of the most interesting events in malaria, and one that links it with bacterial infections, is the reaction of the colourless cells of the blood. It has been shown that during the apyrexial stages the total number of leucocytes varies greatly, but that there is always an increase of the mononuclear cells, these frequently numbering 20 per cent. or more of the whole, and sometimes even outnumbering the polymorphs. This is such an important feature that in cases where the parasites themselves cannot be demonstrated in the blood, the mononuclear reaction along with the presence of pigment in the mononuclear cells (due to phagocytosis of pigmented parasites) has been taken as evidence that the case is really one of malaria. The mononuclear reaction is specially interesting from the fact that in other protozoal diseases an activity of the same elements has been observed.

The question of the possibility of immunity to malaria being developed naturally arises, and this is especially interesting in the light of the leucocyte reaction which we have seen must be looked on as an element in immunity against bacterial infection. With regard to Europeans developing immunity, it is difficult to speak. In such a malaria-stricken region as the West Coast of Africa, the death-rate in residents of more than four years' standing is less than in the previous years, but this may be due to the survival of the more resistant immigrants. But there can be little doubt that malaria in the negro is a much less serious condition than in the European. Koch from his observations in New Guinea attributes this to the infection of the native children leading to the development of immunity in the adult community. He found, what had been independently noted by Stephens and Christophers in West Africa, that the greater number of the children harboured malarial parasites in their blood. The widespread presence of parasites in children might appear to preclude the possibility that the immunity of the adult is due to survival of the most resistant, but the infant mortality in these regions may be very high, and such a survival may be the real explanation. On the other hand, Koch states that while an immunity appears to exist in native adults in malarial districts, this is only true of those born in the locality,—natives coming from neighbouring non-malarial districts into the malarial region being liable to contract the disease. At present it must be held that the facts available do not enable us to determine the relative

parts played by the development of artificial immunity on the one hand, and the existence of a natural immunity on the other, in relation to insusceptibility to malaria.

Our knowledge on the relationship of blackwater fever to malaria is also in an unsatisfactory condition. Blackwater fever is a condition often occurring, especially in Europeans, in tropical countries. It is characterised by pyrexia, darkly-coloured urine, —the colour being due to altered hæmoglobin pigment,—delirium and collapse, frequently ending in coma and death. By some the condition has been looked on as a separate disease, by others as the terminal stage of a severe malaria. With regard to the former view, no special parasite has yet been demonstrated. Stephens sums up the evidence for the second view by saying that malaria, apart from the occurrence of blackwater fever, is a relatively non-fatal disease; that in the great majority of cases there is direct or indirect evidence of the subject of the condition having suffered from repeated attacks of malaria; that while in all cases there must be an agent at work causing hæmolysis, there is evidence that in many cases there is the possibility of that agent being quinine. Christophers and Bentley came to the conclusion that the essential feature in blackwater fever is an extracellular destruction of red corpuscles in the blood plasma, a lysæmia as they call it, and that this is not directly due to parasitic, osmotic, or chemical actions, but to a specific hæmolysin arising in the body as the result of the repeated blood destruction. They have shown, for example, that the addition of fresh serum (complement) to the red corpuscles of blackwater fever, as well as of malarial, patients may produce ysis, this apparently being due to a substance corresponding to immune-body united to the corpuscles in question. The development of this hæmolysin (autolysin) results from the extensive and repeated destruction of red corpuscles by the malarial parasite. Thus though the latter is not the immediate cause of the lysæmia, which is the essential feature of blackwater fever, it is the means of inducing the development of the hæmolysin. If this view of the process is found to be correct, it would of course explain the relationship of malaria to the condition. They also consider that in the conditions mentioned, *i.e.*, where there has been repeated destruction of an individual's corpuscles by the malarial parasite, the occurrence of lysæmia may be precipitated by an acute attack of malaria especially when under certain circumstances this is associated with the administration of quinine. On this view, however, it still remains to be determined whether the lysis at the onset of

an attack of blackwater fever is due to a sudden liberation of complement or to some other cause. Leishman has drawn attention to the presence of certain chromatin bodies in the protoplasm of the hæmic mononuclears in blackwater fever. The significance of the appearance is not at present elucidated, but they might be of a protozoal nature.

Methods of Examination.—The parasites may be studied by examining the blood in the fresh condition, or by permanent preparations. In the former case, a slide and cover-glass having been thoroughly cleaned, a small drop of blood from the finger or lobe of the ear is caught by the cover-glass, and allowed to spread out between it and the slide. It ought to be of such a size that only a thin layer is formed. A ring of vaseline is placed round the edge of the cover-glass to prevent evaporation. For satisfactory examination an immersion lens is to be preferred. The amœboid movements are visible at the ordinary room temperature, though they are more active on a warm stage. With an Abbé condenser a small aperture of the diaphragm should be used.

Permanent preparations are best made by means of dried films, which are then fixed and stained by one of the Romanowsky methods, as described on p. 111. When such stains are not available, the dried films should be fixed by one of the methods described on p. 93, and then stained by methylene- or thionin-blue.

The fact that in many cases the parasites may be few in number led Ross to devise the "thick film process" for making their recognition more easy. Here about as much blood as is used in a hæmoglobin determination (20 c.mm.) is taken on a slide, and, being spread out only so much as to occupy the area of an ordinary cover-glass, is allowed to dry. The hæmoglobin is removed by treating with distilled water and the preparation is then stained by one of the Romanowsky methods; the parasites can then be readily found. Ross and Thomson have modified the method for enumeration purposes. They take a definite small amount of blood, say 1 c.mm., and discharge it on a slide as one or more droplets, which are dried and treated as above. The whole blood is then carefully searched with an oil immersion lens with the aid of a movable stage, and the total number of parasites present are counted.

APPENDIX D.

AMŒBIC DYSENTERY.

In a previous chapter it has been pointed out that the term "dysentery" has been applied to a number of conditions of different etiology, and the relations of bacteria as causal agents have been there discussed (*vide* p. 382). We shall here consider that variety of tropical dysentery which is believed to be due to an amœba, and hence often known as *amœbic dysentery*.

Amongst the early researches on the relation of organisms to dysentery probably the most important are those of Lösch, who noted the presence and described the characters of amœbæ in the stools of a person suffering from the disease, and considered that they were probably the causal agents. Further observations on a more extended scale were made by Kartulis with confirmatory results, this observer finding the same organisms also in liver abscesses associated with dysentery. Councilman and Lafleur, working in Baltimore, showed that this variety of dysentery can be distinguished from other forms, not only by the presence of amœbæ, but also by its pathological anatomy. The intestinal lesions, to which reference is made below, are of a grave character, mortality is relatively high, and recovery, when it occurs, is protracted on account of the extensive tissue changes. The subject was, however, complicated by the fact that a similar organism—the *amœba coli*—had been previously found in the intestine in normal conditions and in other diseases than dysentery (by Cunningham and Lewis and others), and additional research confirmed these results. The characters of the common amœba of the colon and an amœba of dysentery were carefully worked out by Schaudinn, who recognised them to be quite distinct species, and gave to them the names of *entamœba coli* and *entamœba histolytica* respectively. Viereck afterwards described an entamœba of dysentery, which in the encysted stage divided into four cells, and was for this reason called *entamœba tetragena*. This organism was shown to have

pathogenic properties. The entamœba described by Hartmann under the name *E. africana* is generally recognised as being the same organism. Further research has resulted in its being generally recognised that *E. histolytica* and *E. tetragena* are the same, or rather that there is one organism of dysentery, for which Schaudinn's name of *E. histolytica* has been retained, though its process of encystment corresponds with that originally described in the case of *E. tetragena*. Moreover, a small entamœba, described by Elmassian *E. minuta*, is also now considered to represent merely a stage in the life-history of *E. histolytica*.

Entamœba histolytica, as seen in the stools of acute dysentery,

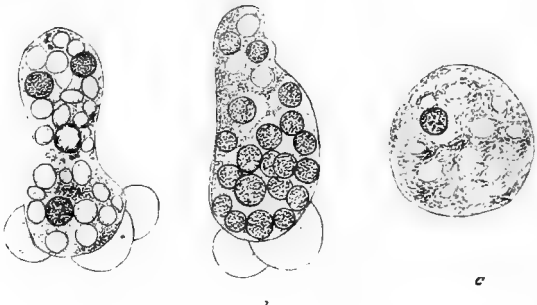

FIG. 187.—Entamœbæ of dysentery.

a and *b*, amœbæ as seen in the fresh stools, showing blunt amœboid processes of ectoplasm. The endoplasm of *a* shows a nucleus, three red corpuscles, and numerous vacuoles; that of *b*, numerous red corpuscles and a few vacuoles.

c, an amœba as seen in a fixed film preparation, showing a small rounded nucleus (Kruse and Pasquale). ×600.

occurs in the form of rounded, oval, or pear-shaped cells, measuring 15–50 μ, usually about 30 μ, in diameter (Figs. 187–194, and Plate VI., Fig. 23). Considerable variations in size are, however, met with. When at rest, a somewhat clear, highly refractile ectoplasm and a granular or vacuolated endoplasm may sometimes be distinguished, though this is not always the case. The nucleus is rounded or oval, and is seen with difficulty; its position is usually excentric, and is sometimes quite at the margin of the endoplasm. In stained specimens it is seen to be poor in chromatin, which is arranged under the nuclear membrane, the latter being ill defined. The pseudopodia, which are quickly protruded and retracted, are blunt and appear to be of a tough consistence, a property which Schaudinn considered of

importance, as enabling the organism to penetrate the mucous membrane, etc. The amœbic movements are often of an active kind, and locomotion may be fairly rapid; and red corpuscles, bacteria, cells, etc., may often be seen in the interior, though the ingestion of red corpuscles is by no means a constant feature. The organism usually dies and undergoes disintegration in a comparatively short time after being removed from the body; the stools ought therefore to be examined in as fresh a state as possible. Multiplication takes place by division into two and, according to some descriptions, also by budding. Schaudinn considered that the former was a direct division, but Werner and Craig have found that it is of mitotic nature. As the

(From drawings by Dr. J. L. Thompson.)

symptoms of the disease abate, the entamœbæ undergo certain changes, which ultimately result in their encystment. The cysts, which are formed when the stools begin to regain their fæcal and formed character, are relatively small, measuring 10–15 μ in diameter; the cyst wall is thin, and within it four, or sometimes only two, nuclei can be faintly seen in the fresh condition (Fig. 188, *c*). In stained specimens the nuclei have the chromatin at the periphery as in the active entamœbæ, but are relatively richer in chromatin. Beside the nuclei one or more elongated chromidial bodies may be seen. Such cysts may be found in the fæces for a long time after dysenteric symptoms have disappeared, and as they are the means of infecting other persons the individuals passing them are to be regarded as carriers dangerous to the community. In the transition from the active amœboid

FIGS. 189–194.—Specimens of *E. histolytica* as seen in the stools in a case of dysentery. The entamœba in Fig. 193 contains two red corpuscles to right of nucleus. Fig. 194 shows a small entamœba ("minuta" form) with two nuclei, richer in chromatin than the others.
Wet film; fixed in sublimate alcohol, stained with hæmatoxylin. × 1000.

form to the cystic stage the following changes occur. The entamœba becomes smaller and the nucleus more distinct and richer in chromatin, though still maintaining its characteristic features. Further diminution in size occurs, the chromatin becoming still more condensed, and the nucleus divides into two or even into four before encystment. These transition forms are to be met with in stools which are losing the typically dysenteric character. Finally the small cell loses its amœboid property and the hyaline cyst-wall forms around it. It is important to note that while the administration of emetine kills off the active entamœbæ with rapidity, it has practically no effect on the encysted forms.

The following is the process of cyst formation as described by Schaudinn. In the earliest stage of the change the nuclear membrane becomes broader and fades into the protoplasm, whilst the chromatin becomes dispersed through the endoplasm in the form of small chromidia. Buds then form on the surface, and into these some of the chromatin passes. Around these buds concentric striation can be seen, and then a hyaline cyst wall is formed, which is highly refractile in character. The cyst then becomes separated from the rest of the cell. Several cysts or encysted spores, which measure 2 to 7 μ in diameter, may be formed from the same amœba, and the remnant of the cell undergoes disintegration. This description was confirmed in the essential points by Craig and by Hartmann. The account given first is, however, that now generally accepted.

The *entamœba coli* is an organism of about the same size as the previous, but on the whole is a little larger. When at rest it shows no differentiation into ectoplasm and endoplasm, and the nucleus, usually situated in the centre, is readily seen, and shows a highly refractile membrane with chromatin masses scattered in the interior. The protoplasm is somewhat granular, and in it there are often small vacuoles containing glycogen. During amœboid movement, which is usually sluggish, some delicate processes of ectoplasm come into view. Red corpuscles are rarely found in the interior and only in small numbers. The cellular changes in the encysting of the *entamœba coli* were worked out by Schaudinn. They are of a somewhat complicated character, involving the formation of reduction bodies and copulation of nuclei, but the ultimate result is the formation of a fairly large cyst, which contains from two to eight small cells. As seen in the fresh state in fæces, the cysts measure 15–20 μ in diameter, the cyst wall is distinct and refractile, and in the interior 2–8 nuclei are clearly visible. They are thus distinguishable from those of *E. histolytica.*

Cultivation.—Various attempts have been made to cultivate the amœba of dysentery, and Kartulis considered that he obtained

growth in straw infusions. Within recent years cultures of amœbæ in association with various bacteria have been obtained on agar media by several workers, *e.g.*, Lesage, Musgrave and Clegg, Noc, and others. For this purpose a plain agar without peptone is used.

The medium of Musgrave and Clegg has the following composition :—

Agar	20 grms.
Sod. chloride	·3–·5 grm.
Extract of beef	·3–·5 grm.
Distilled water	1000 c.c.

It is prepared in the usual way and is made 1 per cent. alkaline to phenol-phthalein.

The presence of bacteria seems to be essential for the growth of the amœbæ, and it is found that some species favour growth whilst others act prejudiciously; amongst the former may be mentioned the sp. choleræ, b. subtilis, and various members of the coli group, though organisms from a great variety of sources have been found to be equally efficient.

In such cultures, which are most conveniently made in Petri dishes, the stages of growth and encystment of the amœbæ can be readily studied; many species flourish best at a temperature of about 25° C. Although cultures without bacterial growth have not been obtained, means have been devised to ensure that only one species of amœba is present. For this purpose Musgrave and Clegg select, by means of a low-power objective, an amœba well separated on the agar plate, place it in the middle of the field, then swing into position a high-power objective, and, having ascertained by means of it that the amœba is still there, lower the point of the lens on to the agar. By this means the amœba may have been picked up, and it may then be transferred to a fresh plate. By such and other methods various amœbæ have been cultivated from water, vegetables, etc., and their process of encystment has been observed. But it has not been conclusively shown that these have pathogenic properties, and on the other hand there is no satisfactory proof that either the *E. histolytica* or the *E. coli* has been obtained in culture outside the body.

Distribution of the Entamœbæ.—As already stated, they are usually found in large numbers in the contents of the large intestine in tropical amœbic dysentery. They also, however, penetrate into the tissues, where they appear to exert a well-marked action. In this disease the lesions are chiefly in the large intestine, especially in the rectum and at the flexures, though

they may also be present in the lower part of the ileum. At first there are seen local swellings on the mucous surface, chiefly due to a sort of inflammatory gelatinous œdema with little leucocytic infiltration; soon, however, the mucous membrane becomes partially ulcerated, more or less extensive necrosis of the subjacent tissues occurs, and gangrenous sloughs result. The ulcers thus come to have irregular and overhanging margins, and the excavation below is often of wider extent than the aperture in the mucous membrane. The amœbæ are found in the mucous membrane when ulcers are being formed, but their most characteristic site is beyond the ulcerated area, where they may be seen penetrating deeply into the submucous and even into the muscular coats. In these positions they may be unattended by any other organisms, and the tissues around them show œdematous swelling and more or less necrotic change, without much accompanying cellular reaction beyond a certain amount of swelling and proliferation of the connective-tissue cells. This action of the amœbæ on the tissues explains the character of the ulcers as just described. These lesions are considered to be characteristic of amœbic dysentery.

FIG. 195.—Section of wall of liver abscess, showing an amœba of spherical form with vacuolated protoplasm. From a case published by Major D. G. Marshall. ×1000.

As a complication of this form of dysentery, liver abscesses are of comparatively common occurrence. They are usually single and of large size; sometimes there are more than one, and occasionally numerous small ones may be present. The contents are usually a thick pinkish fluid of somewhat slimy consistence, which is largely composed of necrosed and liquefied tissue with admixture of blood in varying amount. In such abscesses associated with dysentery the amœbæ are usually to be found, and not infrequently are the only organisms present, no cultures of bacteria being obtainable by the ordinary methods (Fig. 195). They are most numerous at the spreading margin, and this

probably explains a fact pointed out by Manson, that examination of the contents first removed may give a negative result, while they may be detected in the discharge a day or two later. The action here on the tissues is of an analogous nature, namely, a necrosis with softening and partial liquefaction, attended by little or no suppurative change. There is, however, evidence that the amœbæ may infect the liver without causing actual abscess formation, merely a hepatitis, and that this may be followed by cirrhosis. Abscesses are also met with in the lungs, and in such cases the amœbæ have been found in the sputum; as also when a liver abscess has ruptured into the lung, which not very infrequently happens. There have also been recorded a considerable number of cases of cerebral abscess in which the amœbæ have been found; most of these have been secondary to lung infection.

Experimental Inoculation.—Dysentery occurs occasionally in animals, *e.g.*, in monkeys, but it is of comparatively rare occurrence. The disease sometimes results in the dog by experimental inoculation with dysenteric material. Kartulis, for example, records two cases, in one of which liver abscess was present. Cats are, however, found to be more susceptible, especially young animals. Dysenteric changes have been produced in this animal by Kartulis, Kruse and Pasquale, and others. The method generally adopted is the introduction of a small quantity of mucus from a dysenteric case into the rectum. The resulting disease is of an acute character, and sometimes leads to a fatal result. The changes in the large intestine resemble those found in the human disease, and microscopic examination shows the amœbæ penetrating the wall of the bowel in the characteristic manner. Kruse and Pasquale obtained corresponding results when the material from a liver abscess, containing amœbæ without any other organisms, was injected. Quincke and Roos obtained no effects when the amœbæ were administered by the mouth, but they obtained a fatal result in two out of four cases when the cystic forms were given. Schaudinn obtained from China dysenteric material containing cysts and, after drying thoroughly portions of it and administering it to cats, was able to produce typical dysentery, the *E. histolytica* being found in the stools. The most important experiments, however, are those carried out by Walker and Sellards on the human subject. They administered to Filipinos, who acted as volunteers, various amœbæ and entamœbæ or their cysts, the material being mixed with magnesium oxide or starch, and enclosed in gelatine capsules. In the case of the cultivable amœbæ, they found

that though they might be detected in the fæces after feeding with them, none of them became parasites and no pathogenic effects were produced by them. The following were the results with the *E. histolytica*: Of twenty volunteers eighteen were fed with the cysts, two being kept as controls, and of these seventeen became parasitised after one feeding and one after three feedings, the cysts persisting in the stools. Of these, four contracted dysentery, the average period of incubation being sixty days. These results are of great importance both in demonstrating the pathogenic properties of the *E. histolytica* and also in showing that it may become an intestinal parasite without causing dysenteric symptoms and lesions. They also found that, in the cases where dysentery developed, changes occurred in the organisms similar to those observed in the cure of the natural disease, but in the reverse order. They conclude that the *E. histolytica* is a strict parasite, and that the source of infection is always another individual harbouring the organism in the intestine, with or without symptoms of disease.

In the case of the *E. coli* Walker and Sellards were able to bring about parasitism by feeding with the cysts of the organism, but no pathogenic effects followed. Their results accordingly confirm the view previously held that it is a harmless organism and that it is frequently present in the intestines of healthy individuals. Schaudinn found that in East Prussia as many as 50 per cent. of the population were infected with it, and confirmatory results with regard to its common occurrence were obtained by Craig in San Francisco.

Methods of Examination.—The fæces in a suspected case of acute dysentery ought to be examined microscopically as soon as possible after being passed, as the entamœbæ disappear rapidly, especially when the reaction becomes acid. A drop is placed on a slide without the addition of any reagent, a cover-glass is placed over it but not pressed down, and the preparation is examined in the ordinary way or on a hot stage, preferably by the latter method, as the movements of the entamœbæ become more active. The addition of a solution of neutral red, 1 : 5000, is recommended by some, as it stains the entamœbæ a pale pink colour. In the examination for cysts, when the fæces have more of a formed character, a small portion of fæces is emulsified in saline or in Lugol's iodine solution, which brings out the nuclei rather more distinctly and stains glycogen granules. The cysts may be conveniently picked out by means of a dry lens and then examined under the oil immersion. In this case immediate

examination of the fæces after being passed is not essential, as the cysts persist unchanged for several days.

For permanent preparations dried films are not suitable, as in the preparation of these the entamœbæ become distorted. Wet films should be used, and a very suitable fixing agent is composed of 2 parts of a saturated solution of corrosive sublimate in normal salt solution and 1 part of absolute alcohol; they are then treated as already described (p. 93). For such films Heidenhain's iron hæmatoxylin has been found to be one of the best stains, but ordinary hæmalum gives quite good results.

In sections of tissue the entamœbæ may be stained by methylene-blue, by safranin, by hæmatoxylin and eosin, iron hæmatoxylin, etc. Benda's method of staining with safranin and light-green is also a very suitable one. Sections are stained for several hours in a saturated solution of safranin in aniline oil water (p. 103), they are then washed in water and decolorised in a ½ per cent. solution of light-green in alcohol till most of the safranin is discharged, the nuclei, however, remaining deeply stained. In this method the nuclei of the entamœbæ are coloured red (like those of the tissue cells), the protoplasm being of a purplish tint.

APPENDIX E.

TRYPANOSOMIASIS—LEISHMÁNIOSIS—PIROPLASMOSIS.

The Pathogenic Trypanosomes.

The trypanosomata are protozoal organisms belonging to the sub-class Flagellata, and many members of the genus have come to be recognised as living in the blood and tissues in various animals, and as causing important disease conditions. As long ago as 1878 the *Trypanosoma lewisi* was observed infesting the blood of rats, and it has been found to be sometimes capable of causing death. Other diseases in which similar organisms have been found are Surra, which occurs in cattle, horses, and camels in India, and which is associated with the *Tr. evansi*; Dourine, a condition affecting horses in especially the Mediterranean littoral (*Tr. equiperdum* or *rougeti*); Mal de Caderas, a disease of South American horses (*Tr. equinum* or *elmassiani*); Tse-tse Fly Disease or Nagana, affecting horses and herbivora in South Africa (*Tr. brucei*); trypanosomiasis of African cattle (*Tr. theileri*); and—most important from the human standpoint—the trypanosomiasis and sleeping sickness of West and Central Africa associated with the *Tr. gambiense* and *Tr. ugandense*, which are now believed to be the same organism. These diseases present many general resemblances to one another. They tend to be characterised by wasting, cachexia, anæmia, fever often of an intermittent type and irregular œdemas, and frequently have a fatal result. In many cases the infective agent has been proved to be conveyed from a diseased to a healthy animal by the agency of blood-sucking insects.

Morphology and Biology of the Trypanosomata.—If a drop of blood containing trypanosomes be examined, the organism will be seen to be a fusiform mass of protoplasm which at one end passes into a pointed flagellum. In the living condition the trypanosome is usually actively motile by an undulatory move-

ment of its protoplasm and a lashing of the flagellum. The size varies, but those mentioned above are about 30 μ long and about 1·5 to 3 μ broad. Much smaller forms exist, however, and one much larger, *Tr. ingens*, which is 7 to 10 μ broad and 72 to 123 μ long, has been described by Bruce. From the fact that in progression the flagellum is in front, the flagellated end is denominated the anterior end of the organism. The method of examining the fresh blood by merely allowing it to spread itself out in a fairly large drop beneath a cover-glass is more likely to reveal the presence of trypanosomes, if these are present in small numbers, than is that of examining stained specimens; but the minuter structure of the organisms can best be studied in dried preparations stained by Romanowsky dyes, such as those of Leishman or Giemsa.

For staining trypanosomata (or the Leishman-Donovan bodies) *in sections* so as to bring out the chromatin structures, Leishman recommends the following method: Sections of 5 μ thickness are made and carefully fixed on slides. The paraffin is very thoroughly removed by melting it before applying the first xylol, and then washing with alternate baths of alcohol and xylol three or four times. The last alcohol is thoroughly washed off by distilled water, and the excess of water is removed with cigarette paper. A drop of fresh blood serum is then placed on the preparation and allowed to soak in for five minutes. The excess is removed by blotting, and the remainder is allowed to dry on the section, which is now treated with a mixture of two parts of Leishman's stain and three of distilled water, and placed in a Petri dish for 1 to 1½ hour. The preparation is very deeply stained, the nuclei being almost black, and decolorisation and differentiation are effected by alternately applying the acetic acid and caustic soda solutions (commencing with the acid) used in the application of the stain to ordinary histological sections (*v.* p. 113), the effects being carefully watched with a low power. The essential part of the method is the application of the blood serum, though what effect this has is not known; Leishman suggests that it restores the normal alkalinity of the tissue.

In preparations stained by the above methods the protoplasm of trypanosomata stains blue, and in some species some parts are more intensely coloured than others. Sometimes it contains violet-coloured granules (chromatin granules), and occasionally there appears in it slight longitudinal striation. Two bodies are always present in the protoplasm. Usually near the middle there is an oval granular body staining purple,—the trophonucleus or macronucleus,—and towards the posterior end is a minute intensely stained purple granule known as the kinetonucleus, blepharoplast, micronucleus, or centrosome (that this body represents the centrosome is strongly held by Laveran from the analogy of appearances in certain spermatozoa which

closely resemble trypanosomes in structure). This micronucleus is often surrounded by an unstained halo, and in its neighbourhood, in certain species, a vacuole has been described as existing. From the micronucleus or from its neighbourhood there arises an important structure in the trypanosome,—the undulatory membrane. This is of varying breadth, has a sharp undulating free margin, and surmounts the protoplasm of the organism like a cock's comb; it narrows towards the anterior end, where it becomes the flagellum. Motion is chiefly effected by the undulations of this membrane and of the flagellum. The latter is continuous with the protoplasm of the body of the organism; it stains uniformly like it, except the free edge which has the reddish hue of the chromatin. In different species of trypanosomes, variations occur in shape, in length, in breadth, in the position of the micronucleus (and therefore in the length of the undulating membrane), in the breadth of the membrane, in the length of the free part of the flagellum, in the shape of the posterior end, which is sometimes blunt, sometimes sharp, and in the presence or absence of free chromatin granules in the protoplasm. It may be said that the differentiation of species of trypanosomes is often a task of great difficulty, as both morphological and experimental study is necessary.

Multiplication in the body fluids ordinarily occurs by longitudinal, amitotic division. First of all, the micronucleus divides, sometimes transversely, sometimes longitudinally, then the macronucleus and undulating membrane, and lastly the protoplasm. In some species the root of the flagellum only divides, so that in the young trypanosomes the flagellum is short and subsequently increases in length (Tr. lewisi); usually the whole flagellum takes part in the general splitting of the organism. In certain cases reproduction occurs by the endogenous formation in the nucleus of chromidial buds (Minchin). These buds are the "infective granules" of Henry and other observers, and when extruded from the protoplasm develop into trypanosomes.

In most cases in the circulating blood the parasites of a species show differences in shape and size; usually there is a form long and slender in both body and nucleus, the free part of the flagellum being longer than the body and the protoplasm free from granules. In another type the organism is broader, with a larger and rounder nucleus and a blunter posterior extremity; the undulating membrane is narrow and the free part of the flagellum is shorter than the body, and the protoplasm contains granules. According to one view, the former is

the male form and the latter the female, and intermediate or indifferent types are also seen. Whether any significance is to be attached to the occurrence of these different types is at present unknown, but it is probable that some of them have more vegetative activity than others, and the prevalence of these is related to the infectivity of the blood when transferred to a new host. Further, in especially chronic infections the number of organisms present in the peripheral blood varies, and thus the potentiality of infection by means of an invertebrate carrier also varies. When the organisms are absent from the blood they may still be found in the solid organs and in the bone marrow, and in such situations may go through a resting phase of development. In Tr. cruzi such a stage has been demonstrated in endothelial cells, and a similar condition has been observed in Tr. brucei in the gerbil.

The outstanding fact in the biology of the pathogenic trypanosomes is that infection from vertebrate to vertebrate takes place by the parasite being transferred by the agency of biting or blood-sucking insects, or by leeches. The mere mechanical transference by such invertebrates is possible, and in certain cases a multiplication of the organism in the biting apparatus of the invertebrate occurs. Such a mechanical or semi-mechanical transference plays, however, a subsidiary part in ordinary infections, for in many cases a considerable period may elapse between, *e.g.*, an insect taking up infective blood and becoming itself infective for new hosts. Here the parasite undoubtedly goes through a cycle of development within the invertebrate, the details of which are in many instances as yet undetermined. In the blood taken up, the trypanosomes are seen to undergo modifications in form. They may show simple division by which the resulting individuals become smaller,—the relation of kinetonucleus and trophonucleus may be altered,—and the undulating membrane and flagellum become rudimentary (crithidial forms). In other cases, organisms resembling Leishmaniæ result. The stage in the cycle at which the organism again becomes infective for the vertebrate host differs in different instances.

There are probably great differences in the cycles of trypanosomes within the vertebrate and invertebrate hosts, and controversy has turned round the question of whether a sexual conjugation occurs. This has been described in connection with the so-called male and female adult forms of the trypanosome already described, and also in connection with crithidial forms. While the analogy of what happens in the malarial parasite

suggests the possibility of a sexual element in a trypanosomal cycle, there is at present no definite proof that such a stage has ever been observed. The occurrence of cyclic phases does not necessarily involve the interposition of conjugation.

It has been found possible to cultivate a great number of the trypanosomata outside the bodies of their natural hosts, the first work having been done by Novy and MacNeal, who introduced a special medium for the purpose (p. 46). In cultures, the organisms may divide longitudinally, as seen in the blood, or crithidial or Leishmania forms may result, the former being often arranged in rosettes containing a large number of individuals with their flagella pointing in one direction. A fresh infection may sometimes be originated by introducing such cultures into suitable animals.

While many trypanosomes give rise to serious disease, in many cases a heavy infection may occur without the animal suffering any apparent inconvenience, and a form producing disease in one species may be present in considerable numbers in another species without causing any pathogenic effects.

We now pass to consider in detail some of the more important trypanosomes.

Trypanosoma lewisi.—This trypanosome, which Lewis in 1878 described in India, has been found to be very common in the blood of rats all over the world, though the percentage of animals affected varies in different localities. The organism has no importance from the standpoint of human pathology, but the condition in the rat is of great interest, as, though the infection runs a very definite course, it is very rarely fatal; in fact, most observers have been unable to produce death by infecting even large series of animals. A fatal issue may, however, occur in young individuals, especially when these are infected with strains of the organism imported from other localities. The trypanosome, which is actively motile, is of ordinary length but is somewhat narrow, and its protoplasm does not contain any granules. It multiplies by fission, of which Laveran describes two varieties. In one, the organism splits longitudinally and gives rise to smaller individuals than the parent. In the other, the trypanosome loses its ordinary shape and becomes more oval: nuclear division, which is often multiple, then takes place, and on subsequent division of the protoplasm a number of small flagellate organisms result; these last may attain the full form and size before dividing again, or they may divide when still small. When a rat is infected by injection into the peritoneum, active multiplication goes on in the cavity for a few days and then comes to an end. Very soon after infection the organisms begin to appear in the blood and there rapid multiplication occurs, the extent of which is sometimes so great that the trypanosomes may seem to equal the red blood corpuscles in number. The animal usually shows no symptoms of illness. The infection goes on for about two months, and then the organisms gradually disappear from the blood. In the great majority of cases the rat is now immune against fresh infection. If trypanosomes be introduced into its

peritoneum they are, according to Laveran, taken up by mononucleate phagocytes and destroyed. The serum of a rat which has been infected shows agglutinating capacities towards the trypanosomes, causing them to agglomerate in rosettes in which the flagella are directed outwards, and the serum of immune rats has a certain degree of protective action if injected along with the organism into a susceptible animal. As has already been noted, this trypanosome has been cultivated on artificial media, on which it multiplies freely, large numbers of small forms being often produced. These when injected into rats give rise to the usual infection, but not so rapidly as when blood from an infected animal is used. The organism multiplies at the body temperature, but a lower temperature is preferable, and at 20° C. Novy and MacNeal succeeded in carrying a growth through many sub-cultures. The trypanosome is very resistant to cooling, and has been exposed for fifteen minutes to the temperature of liquid air (−191° C.) without being killed. Minchin and Thomson have shown that the rat flea, *ceratophyllus fasciatus*, transmits the parasite by the cyclical method, infection probably occurring through the fleas or their fæces being swallowed. The flea becomes infective about a week after biting, and remains infective for the rest of its life. Infection may also take place through another species of flea and through a louse.

Nagana or Tse-tse Fly Disease.—This is a disease affecting under natural conditions chiefly horses, cattle, and dogs; it is prevalent especially in certain regions of South Africa, though it probably may occur elsewhere. In the horse the chief symptoms are the following: The animal is observed to be out of condition, its coat stares, it has a watery discharge from the eyes and nose, and the temperature is elevated; swellings appear on the under surface of the abdomen and in the legs; it gradually becomes extremely emaciated and anæmic, and dies after an illness of from two or three weeks to two or three months. In other animals the symptoms are of the same order, though the duration of the disease varies much; thus in the dog the illness does not last more than one or two weeks, while in cattle it may continue for six months. It is doubtful whether a domestic animal attacked by the disease ever recovers. The popular idea regarding the etiology of the disease was that it was contracted by animals passing through certain rather restricted and sharply defined areas or belts characterised by heat and damp, sometimes lying beside rivers, and always infested by the tse-tse fly (*glossina morsitans*), to the bite of which the disease was attributed; in this connection it is important to note that though man is frequently bitten by the tse-tse fly he does not contract nagana. This statement may, however, require modification if Tr. rhodesiense (*v. infra*) prove to be a strain of Tr. brucei. Modern knowledge on the subject dates from the discovery made by Bruce in 1894 that the blood of animals suffering from nagana swarmed with a trypanosome now known as the Tr. brucei, and in 1895 he was instructed by the Governor of Natal to undertake the investigation which led him to work out the true etiology of the disease. It may be said that this research forms the starting-point of the important work done within recent years with regard to infections by trypanosomes. In his earlier work, Bruce found that the parasite was present in the blood of every animal suffering from nagana and absent from the blood of healthy animals in the affected districts; further, that the fever which marks the onset of the disease was accompanied by the appearance of the trypanosome in the blood; and

finally, that the transference of the smallest quantity of blood from an affected to a healthy animal originated the disease. He then proceeded to investigate the part played by the tse-tse fly in the condition. He found that if flies taken from the fly belt, but which had not fed on an infected animal, were transported to a place where nagana did not occur, kept for a few days, and then allowed to bite susceptible animals, the latter did not contract the disease—this result showing that it was not, as had been supposed by some, a poison natural to the insect which was the pathogenic agent. But if such a fly was allowed to bite a dog suffering from the disease and then to bite a healthy dog, the latter contracted the malady and abundant trypanosomes were found in its blood. Again, threads dipped in the blood of an infected animal and allowed to dry caused the disease in healthy animals up to, but rarely beyond, twenty-four hours after being dried; if, however, the blood were kept moist, then it retained its infectiveness up to between four and seven days; up to forty-six hours living trypanosomes could be seen in the tube of the fly's proboscis. Further, Bruce showed that infection did not occur by any food or water partaken of by an animal while going through a fly belt, for he took horses through such a region without allowing them to eat or drink, and found that they still contracted the infection, if during their few hours' journey through the belt they had been bitten by the tse-tse fly. Finally, he showed that if flies were taken from an infected area to a healthy one a few miles off and allowed to bite infected animals, the latter contracted nagana.

By those experiments it was thus determined that nagana could be transmitted by the blood of the infected animal—that is, without the agency of the fly; that the latter had no inherent power to produce the disease; that it could, however, by successively biting infected and healthy animals, transmit the disease to the latter; and that specimens of the insect caught in infected areas harboured the parasite and were thus infective. The question remained as to how the flies might become infected in nature. It had been observed that in districts where the tse-tse fly lived, the prevalence of the disease in imported animals was related to the presence in the locality of wild herbivora. Bruce now found that, if considerable amounts of the blood of the latter were taken to another locality and injected into dogs, these in a proportion of cases contracted nagana, and from this he deduced that the wild animals harboured the parasites in small numbers in their blood and thus kept up the possibility of infection. Bruce's work as a whole pointed to the trypanosome as the cause of nagana, and this has since been finally established by the origination of the disease by artificial cultures of the organism. It is doubtful whether the glossina acts as a mere mechanical carrier, as there is evidence that the trypanosome undergoes a cyclic development in the body of the insect.

The Tr. brucei (Fig. 196), according to Laveran, measures in the horse from 28 to 33 μ long and from 1·5 to 2·5 μ broad; in the rat and dog it is somewhat shorter. It is motile, but its activity is less than that of Tr. lewisi. When stained it presents the usual appearances; its posterior end is usually blunt, and the body often contains granules in the anterior portion of its protoplasm. It divides longitudinally, and, according to Bradford and Plimmer, a form of longitudinal conjugation occurs in the blood. According to the same observers, it can be kept alive for five to six days in blood outside the body. It is less resistant to the action of cold than Tr. lewisi, perishing in a few days at 5° to 7° C., but, like the

other organism, it can withstand short exposures to temperatures down to – 191° C. ; it is quickly killed at 44° to 45° C. Novy and MacNeal succeeded in cultivating this trypanosome also, though here it was very difficult to obtain a first growth from the blood on their blood-agar medium ; once started, however, it was kept alive through many sub-cultures, the optimum temperature of growth being 25° C., and it was from these sub-cultures that the infection was obtained which definitely proved the organism to be the cause of the disease. In cultures, as with Tr. lewisi, short forms occur, and there is sometimes a rosette formation

FIG. 196.—Trypanosoma brucei from blood of infected rat. Note in two of the organisms commencing division of micronucleus and undulating membrane. ×1000.

with the flagella directed outwards ; agglutination phenomena are also observable in defibrinated blood. Under favourable conditions, involution forms occur, the organism dividing frequently to form round flagellated individuals.

Nearly all laboratory animals are susceptible to infection, and the duration of the illness corresponds to what has been observed in the natural infection of these animals. The rat has been largely used for experiment and usually succumbs in about ten days, there being very few symptoms up to a few hours before death. A very important fact has been observed with regard to this animal, namely, that individuals which have gone through infection with Tr. lewisi and which are immune

are still susceptible to the Tr. brucei; from this it has been deduced that the two organisms are to be looked on as distinct species.

Trypanosoma of Sleeping Sickness.—Since the year 1800 the disease called sleeping sickness, sleeping dropsy, or negro lethargy has been recognised as prevailing on the West Coast of Africa from the Senegal to Lagos, and in the parts lying behind the coast between these regions. It has also been found to be rife from Cameroon to Angola and in the Congo valley, and to a less extent up the Niger and its tributaries. In 1901 it began to appear in the Uganda Protectorate, where it has wrought very serious havoc amongst the native population, and the investigations carried on in that region have led to a knowledge of its cause. The disease is characterised in the early stages by a change in disposition leading to moroseness, apathy, disinclination for work or exertion, and slowness of speech and gait. There may be headache, indefinite pains about the body, the evening temperature may be elevated several degrees, the pulse tends to be soft and rapid, and in a very large number of cases the superficial glands of the body are enlarged. In a rapid case the lethargy becomes more pronounced; fine tremors, especially of the tongue and arms, develop; progressive emaciation occurs; blood changes appear, consisting of a progressive diminution of the red cells and of the hæmoglobin, and of a lymphocytosis in which the percentage of both the large and small mononuclear cells is increased, so that the former may constitute from 20 to 30 and the latter from 30 to 40 per cent. of all the white cells present. As the disease progresses the drowsiness increases till it deepens into a coma from which the individual cannot be roused. Often during the disease there occur irregular œdematous patches on the skin, and sometimes erythematous eruptions, and effusions into the serous cavities. Not every case runs a progressively advancing course. Sometimes along with enlargement of glands the chief early feature is the occurrence from time to time of attacks of fever which may be mistaken for malaria, and from these apparently complete recovery may take place; recurrence, however, follows as a rule, and ultimately the typical terminal phenomena may commence. Such cases may go on for years, and it is probable that many patients die of pneumonia without exhibiting typical manifestations of the malady from which they really suffer. The disease is an extremely fatal condition, and probably no case where the actual lethargy is developed ever recovers.

On considering the disease from the standpoint of pathological anatomy there is little to be said. As Mott described, the most

striking feature is the presence of a chronic meningo-encephalitis and meningo-myelitis. The pia-arachnoid is sometimes opaque and slightly thickened and may be adherent to the brain, and its vessels usually show some congestion. The sub-arachnoid fluid is sometimes in excess and occasionally may even be purulent. The membranes of the spinal cord show similar changes. The chief other feature is the presence of enlarged lymphatic glands in the body, but otherwise there is nothing special to note. With regard to the microscopic changes, the chief feature, according to Mott, is a proliferation and overgrowth of the neuroglia cells, especially of those which are related to the sub-arachnoid space and the perivascular lymph spaces, with accumulation and probably proliferation of lymphocytes in the meshwork. He further points out that the changes in the lymph glands are of similar nature to and resemble the infiltration of the perivascular lymphatics of the central nervous system. These changes are specially significant in view of the lymphocytosis present in the blood, which has already been noted, and which so often occurs in protozoal infections. In the nervous structures there is comparatively little change, there being merely, according to Mott, some atrophy of the dendrons of the nerve cells, a diminution of Nissl's granules, and an excentricity of the nucleus.

Trypanosoma gambiense.—Before going further we must refer to the observation of a trypanosome in the blood of persons not evidently suffering from sleeping sickness. The first case of this was recorded by Dutton in 1901, the patient being a European then living at Bathurst on the Gambia. The progress of the disease was here very slow, and was characterised by general wasting and weakness, irregular rises of temperature, local œdemas, congested areas of the skin, enlargement of spleen, and increased frequency of pulse and respiration; death occurred a year after the case came under observation after an access of fever, and a striking fact was the absence of any gross causal lesion. During the time the patient was under observation trypanosomes were repeatedly demonstrated in the peripheral blood, and they also developed in the bodies of monkeys and white rats inoculated with the blood. Pursuing further inquiries, Dutton and Todd demonstrated similar parasites in other Europeans and in several natives in the Gambia region, whilst about the same time Manson reported a case of the same kind in the wife of a missionary on the Congo. It thus came to be recognised that in man there occurred a disease having characters somewhat resembling nagana and in which trypano-

somes could be demonstrated in the blood, and this was usually referred to as human trypanosomiasis, or trypanosoma fever,—the trypanosome being named the Tr. gambiense.

Relation of Trypanosomes to Sleeping Sickness.—Several views as to the etiology of this disease had been advanced, and the seriousness of the epidemic in Uganda led the Royal Society of London in 1902, at the instigation of the Foreign Office, to dispatch a Commission to investigate the condition on the spot. Soon after its commencing work, Castellani found in some cases in the cerebro-spinal fluid, especially when this was centrifugalised, living trypanosomes resembling the Tr. gambiense; he also found in 80 per cent. of the cases *post mortem* a coccus previously described by other observers. At first Castellani was inclined to look on the presence of the protozoon as accidental, but Bruce, on going out with Nabarro and Greig in 1903 to pursue the work of the Commission, realised the significance of the observation, urged Castellani to further inquiries, which he himself continued after the departure of the latter, with the result that, in a series of examinations carried out in several infected localities, the trypanosome was demonstrated in every case of the disease. This work formed the starting-point for inquiries, the results of which make it certain that the parasite is the causal agent of the condition. The organisms were not demonstrable in the cerebro-spinal fluid of patients dying of other diseases in the sleeping sickness area. On the other hand, it was found that if cerebro-spinal fluid withdrawn from cases of the disease was injected into monkeys (especially *macacus rhesus*), trypanosomes appeared in the blood, and in many cases in three or four months the animals died of an illness indistinguishable from sleeping sickness, and with the parasites in the central nervous system. It was further found that in the parts round the north end of Victoria Nyanza where sleeping sickness was rife, the distribution of the disease exactly corresponded with the distribution of a blood-sucking insect, the *glossina palpalis*, a species closely allied to the *glossina morsitans* of nagana. It was found that, when one of these flies was fed on a sleeping sickness patient and then allowed to bite a monkey, frequently trypanosomes appeared in the animal's blood, and that when fresh flies caught in the sleeping sickness area were placed on a monkey a similar occurrence often took place.

The trypanosome of sleeping sickness is 13 to 33 μ long (average in man 24·3 μ) and 1·5 to 2·5 μ broad (Fig. 197); when about to divide it grows in both length and breadth. According to Laveran, the free part of the flagellum often equals

a fourth of the whole length, but occasionally the body protoplasm extends quite to the anterior end of the organism. The undulating membrane is narrow, and the posterior end may be either sharp or blunt. The trypanosome contains the macro- and micro-nucleus characteristic of the group, and the protoplasm often shows chromatin granules. It does not usually long survive removal from the body, but it has been found to be motile for nineteen days when kept on rabbit-blood agar at 22° C. As we

FIG. 197.—Trypanosoma gambiense from blood of guinea-pig. ×1000. See also Plate VI., Fig. 25.

have said, when Tr. ugandense is inoculated in monkeys they often contract an illness which ultimately presents the features of typical sleeping sickness. In inoculation of other species of animals, *e.g.*, herbivora, the guinea-pig, in nearly every case a proliferation of the parasite, as indicated by its appearing in the blood, takes place; but often either no disease occurs or this runs a very chronic course.

By means of microscopic examination the organisms may be found in the cerebro-spinal fluid, the blood, or the juice of

glands. In the case of the first, about 10 c.c. of the fluid is to be centrifugalised for fifteen minutes and the deposit placed under a cover-glass for examination; it is better to make a little cell on a slide by painting a ring of ordinary embedding paraffin, to place the droplet of fluid in its centre, and to support the cover-glass on the paraffin; in this way injury to the delicate structure of the organism is avoided. In fresh cerebro-spinal fluid the trypanosomes can be seen to be actively motile; the number in which they occur varies very much, and the same is true to a greater degree of the blood, in which they are, however, usually very scanty. With regard to the examination of the blood, Bruce and Nabarro state that it is difficult by ordinary centrifugalisation to concentrate the organisms, as these are not readily precipitated. They accordingly recommend that the blood be mixed with citrate of sodium solution (equal parts of blood and of a 1 per cent. citrate solution) and centrifugalised for ten minutes, that the plasma be removed and centrifugalised afresh for the same time, and that this be repeated three times, the deposit from each centrifugalisation after the first being carefully examined. Greig and Gray have insisted that the examination of the glands in a suspected case forms the most ready means of arriving at a diagnosis, and this opinion has found strong support from the work of Dutton and Todd. The method is to push a hypodermic needle into the gland, suck up a little of the juice, and blow it out on to a slide. In all cases where films of any kind are to be prepared the staining methods of Leishman or Giemsa are to be recommended. Often in cerebro-spinal fluid and gland juice the staining of the chromatin is difficult, but good preparations are obtained by the procedure recommended by Leishman for studying the parasite in sections (p. 113).

Greig and Gray found evidence of the trypanosome multiplying in the stomach of the glossina, and it also was seen to undergo changes not observed elsewhere. These consisted in alterations in the position of the micronucleus, which often became anterior to the macronucleus; there also occurred rosettes, consisting of from four to twenty individuals attached by their posterior extremities. Oval forms were also observed. It was at first supposed that monkeys could not be inoculated with the trypanosomes from the bruised-up bodies of the fly, but Bruce succeeded in originating an infection with this material, results being positive during the first two days after the fly had bitten and then being negative till after the twenty-second day; probably, however, the organism remains alive in only a small pro-

portion of flies biting an infective case. Minchin in this connection described in the gut of the fly different types of the parasite, and Koch and Kleine also found in the intestine agglomerations of immature forms which they ascribed to the results of sexual conjugation. The most important fact established by the last observer was, however, that when Gl. morsitans was allowed to bite an animal suffering from nagana it did not become infective for some days. This has been confirmed for Gl. palpalis, in the case of monkeys suffering from Tr. gambiense, by Bruce and those associated with him in 1908–9. Here it was found that infectivity did not appear till about thirty-two days after the fly had fed, and continued until at least seventy-five days. Bruce noted that the renewed infectivity corresponded with the appearance of perfect trypanosomes in the salivary gland of the glossina. In this connection certain facts having a serious bearing on the continued infectivity of a locality have emerged. It was found that a certain island on Lake Victoria Nyanza, which had been cleared of infective natives two years previously, still harboured infective flies. To account for this it must be supposed either that the glossina has an extended duration of life, or that the trypanosome exists among the wild animals. It has been found that cattle and wild herbivora can be infected with the parasite, and can through the medium of the fly infect monkeys. It is possible that such animals, while not suffering in any serious way themselves, are the means of maintaining infectivity. There is no definite evidence that, as Koch supposed, the crocodile harbours the trypanosome.

Early in the Uganda investigations the question arose as to whether the trypanosome of sleeping sickness was different from Tr. gambiense. This was forced on the inquirers by the fact that a large proportion of the natives in the sleeping sickness area were found to harbour trypanosomes in their blood, although not apparently suffering from the disease. Several cases were carefully examined in which trypanosomes were constantly present in the blood, but in which the patients from time to time suffered from fever, and during these pyrexial periods trypanosomes were found in the cerebro-spinal fluid. It was suggested that these cases were on the way to develop sleeping sickness. A very important observation was that while in sleeping sickness areas a large proportion of the native population harboured trypanosomes, this was not the case where sleeping sickness did not occur. Further, it was found that trypanosomes from the cerebro-spinal fluid of sleeping sickness cases and from the blood of persons harbouring trypanosomes,

but not suffering from disease symptoms, gave rise in monkeys to the same group of chronic effects which resembled the last stages of the disease in man. These facts led the Commissioners to incline to the idea that trypanosome fever and sleeping sickness are due to the same cause, and represent different stages of the same disease. It has already been pointed out that a fatal termination can occur in trypanosome fever by an acute febrile attack or from intercurrent disease, and thus the terminal lethargic stage may only develop in a certain proportion of cases. Continued observation of prolonged cases of trypanosome fever, both in Uganda by Greig and Gray, and in this country by Manson, has shown that sometimes the termination of a case is by the onset of typical sleeping sickness. There is now practically no doubt that the two conditions are etiologically identical. The best authorities are agreed that morphologically no difference between the Tr. gambiense and the Tr. ugandense can be recognised, and from considerations of priority the former term is now alone employed.

The prevalence of trypanosomes in the blood of apparently healthy natives has raised the question of the possibility of tolerance existing and of immunity being established. It is possible that both phenomena occur, that not every infection results in multiplication of the parasite in the body of the victim, and that in certain cases where multiplication does occur a resistance is developed which enables the body to kill the parasites. The occurrence of the mononuclear reaction is here significant; it has been suggested that, when this resistance is weak, the organism gains entrance to the spinal canal, and that then sleeping sickness results.

The work on the disease is of the highest interest and importance. It is practically certain that the Tr. gambiense is the cause of sleeping sickness, and action taken on this supposition has checked the ravages of the disease in Uganda, where the natives have been deported from the fly areas, and the brushwood in which the insects lodge has been cut down in the neighbourhood of paths and ferries.

Trypanosoma rhodesiense.—In 1910, Stephens and Fantham observed certain peculiarities in the trypanosomes derived from a case of human trypanosomiasis occurring in an individual who had returned to England from Rhodesia. The organisms frequently presented a very blunt posterior extremity and the trophonucleus tended to approach the kinetonucleus and in certain cases to lie behind it. Another feature of the case was that only Gl. morsitans, which up till then had not been sus-

pected of being capable of transmitting trypanosomiasis to man, prevailed in the regions through which the patient had travelled. Shortly thereafter a serious outbreak of trypanosomiasis was reported from the country west of Lake Nyassa, and it is now known that the disease prevails on several of the northern tributaries of the Zambesi, in the adjacent parts of the Belgian Congo, and even in Portuguese East Africa in districts where only Gl. morsitans and not Gl. palpalis prevails. It was, however, shown by Kinghorn and Yorke, working on the Luangwa (a tributary of the Zambesi), that Gl. morsitans could transmit trypanosomes from human cases to rats, the cycle in the fly being about eleven days, and that a definite percentage of wild flies in this region harboured the human parasite. There is thus no doubt that man, in widely extended regions of southern Central Africa, is exposed to danger when bitten by Gl. morsitans. Further, the opinion is generally accepted that Tr. rhodesiense is a species distinct from Tr. gambiense. The disease in man tends to be more acute; there is frequently not a terminal sleeping sickness stage, and there is less pronounced infection of lymphatic glands. The organism is also more virulent for animals, the duration of the illness being shorter and the susceptibility of the sheep and goat is greater than towards Tr. gambiense. In both of these animals widespread œdema, especially of the face, is a marked characteristic. The organism has been cultivated on Novy and MacNeal's medium. There has been considerable controversy regarding the relationship of Tr. rhodesiense to Tr. brucei. While differences in the pathogenic effects of the two organisms have been observed, the right interpretation of the data constitutes a difficult question. Bruce and his co-workers, founding largely on extended biometric investigations, are of opinion that the Tr. rhodesiense is a strain of Tr. brucei which has adapted itself to man, and this view is now widely held. A number of other strains of trypanosomes have been recognised in human cases, and the relationship of these to the more fully determined forms has been the subject of much investigation.

Not much success has attended remedial efforts in those suffering from trypanosome infection. Here attention has been chiefly concentrated on the action of organic arsenical compounds (salvarsan, galyl, etc.), the application of which in the shape of atoxyl was first recommended by Thomas. A great range of such substances and also of aniline derivatives was investigated by Ehrlich and his co-workers, and under certain conditions of artificial infection in animals a complete or partial destruction

of the parasites followed administration of these bodies, but their application to natural infections has not as yet met with decided success. Sufficient, however, is known to justify further investigations of a similar kind. It has been observed that a tolerance of such reagents can be developed by the trypanosomes, and this fact may complicate the problem at issue.

Both normal serum and the serum of infected animals have been found to possess trypanocidal and protective properties, and in certain cases a degree of immunity has been established as the result of light infections. It has not hitherto been possible, however, to produce such a degree of immunity as could be utilised either for prophylactic or therapeutic purposes. The serum of an infected animal may manifest a specific agglutination reaction towards the infecting trypanosome.

Other Pathogenic Trypanosomes.—Apart from sleeping sickness no other important disease of man has been found to be associated with trypanosomal infection, but some observations on a condition observed in Brazil may be alluded to.

Trypanosoma cruzi.—Chagas, working in Brazil, observed this trypanosome in a monkey, the intermediate host being hemipterous insects of the genus *Conorhinus*. As these insects also feed on man, the possible relationship of the trypanosome to a human disease occurring in that region was considered. This disease affects children, and gives rise to pronounced anæmia, the occurrence of œdema, and enlargement of lymphatic glands, the spleen, and liver; it may cause death in a few weeks, or assume a chronic form lasting for years and characterised by disorders of internal secretion (myxœdema, bronzing of skin) and infantilism. The trypanosome is not found in large numbers in the peripheral circulation in such cases, but when the blood is injected into guinea-pigs, or into callithrix monkeys, a definite disease occurs, leading to death. The special feature of interest is the development of the parasite occurring in the lungs of guinea-pigs. Here within the endothelial cells the organisms assume a round or pyriform shape with one nucleus which divides to form eight bodies resembling somewhat the merozoite form of the malarial parasite. It is supposed that these escape and infect the red blood cells, as in the circulating blood erythrocytes containing merozoite bodies are present, and from these a trypanosome develops within the red cell. *Post mortem* in man, the parasite occurs chiefly in the cardiac and voluntary muscles and in the central nervous system, in which situations the tissue cells may contain enormous numbers of the organism in a small round or pear-shaped form with tropho- and kineto-nuclei but no flagellum or undulating membrane. A cycle of development also takes place in the intestinal tube of the conorhinus, and cultures are obtainable on Novy and MacNeal's medium. There is little doubt that the trypanosome is the cause of the disease.

It is beyond the scope of this work to deal at length with the other diseases of animals caused by trypanosomes. The chief of these have been mentioned in the opening paragraph, but it may

be said that many others have been described in various species of mammals, birds, and fishes, and that these are spread either by flies or by leeches. The most interesting of those mentioned is Dourine, a condition resembling in many ways nagana. It, however, presents this peculiarity, that infection does not take place by an intermediate host, but apparently directly through coitus, as it occurs only in stallions and in mares covered by these.

In several of the trypanosomal infections of animals it appears as if, as in the case of Tr. lewisi, the animal suffers little inconvenience from the presence of the parasite in its blood, and the view has even been put forward that in many pathogenic trypanosomes there exists a host which acts as a "reservoir" and carries the organism without being affected by its presence more than, for example, is the rat by Tr. lewisi. Though no opinion can be expressed on this point, it is necessary to bear the fact in mind that either natural or acquired immunity can exist against such protozoa. Not only is this important from the point of view of the investigation of the conditions under which such tolerance arises, but also from the bearing which the existence of this tolerance may have on the spread in nature of the parasites to a susceptible species from immune animals which still harbour trypanosomes in their blood. We are, however, as yet quite ignorant of many of the processes at work in the body during a trypanosomal infection, and of the causes of the symptoms and other morbid effects.

Leishmaniosis.

Under this term there are grouped three human diseases, but the exact zoological place of the parasites among the protozoa cannot be said to be at present definitely settled. These organisms are the Leishmania donovani, associated with the human disease, kála-ázar ; Leishmania infantum, derived from a similar disease occurring in children ; and Leishmania tropica, which has been found in a skin ulceration of widespread geographical distribution. Microscopically the organisms are practically identical, but at present it is convenient to look upon the three species as being distinct.

Leishmania Donovani.—Leishman noticed in several soldiers invalided from India for remittent fever and cachexia that the most careful examination of the blood failed to reveal the presence of the malarial parasite. From the fact that such patients had almost invariably been quartered during their

service at Dum-Dum, an unhealthy cantonment near Calcutta, he suspected he had to deal with an undescribed disease. In 1900 he noticed in the spleen of such a case peculiar bodies which, from comparison with certain appearances found in degenerating forms of Tr. brucei, he suggested might be trypanosomes, and on publishing his observations in 1903 he put forward the view that trypanosomiasis might prevail in India and account for the aberrant cases of cachexial fever met with there. Soon after Leishman's paper appeared, his observations were confirmed in India by Donovan, and the bodies associated with the disease are usually called the "Leishman" or the "Leishman-Donovan" bodies. They were found by Bentley, and later by Rogers, in the disease known in Assam as kála-ázar, the pathology of which had long puzzled those who had worked at it, from the fact that, while it resembled malaria in many ways, no parasite could be demonstrated to occur in those suffering from it. This disease has gone under various synonyms, *e.g.*, cachetic fever, Dum-Dum fever, non-malarial remittent fever, but is now recognised as a single specific entity.

Kála-ázar (or "black disease,"—so called from the hue assumed by chocolate-coloured patients suffering from it) has been known since 1869 as a serious epidemic disease in Assam, where it has spread from village to village up the Brahmaputra valley. The disease is now known to occur in various sub-tropical centres—cases where the Leishman bodies have been found having been met with in many parts of India, China, Turkestan, the Malay Archipelago, North Africa, the Soudan, Syria, and Arabia. The disease is characterised by fever of a very irregular type, by progressive cachexia, and by anæmia associated with enlargement of the spleen and liver, and often with ulcers of the skin and with transitory dropsical swellings. Rogers has pointed out that there occurs a leucopenia which differs from that of malaria in that it is almost always more marked,—the leucocytes usually numbering less than 2000,—and further, in that the white cells are always reduced in greater ratio than the red corpuscles, which condition, again, does not occur in malaria. The disease is chronic, often going on for several years, and in, at any rate, 80 per cent. of the cases has a fatal issue. *Post mortem*, there is little to note beyond the enlargement of the liver and spleen, but in the intestine, especially in the colon, there are often large or small ulcers, and there is evidence of proliferation in the bone marrow, the red marrow encroaching on the yellow.

In a film made from the spleen and stained by Leishman's

stain, the characteristic bodies can be readily demonstrated (Fig. 198). They are round, oval, or, as Christophers has pointed out, cockle-shell-shaped, and usually 2·5 to 3·5 μ in diameter, though smaller forms occur. The protoplasm stains pink, or sometimes slightly bluish, and contains two bodies taking on the bright red colour of nuclear matter when stained by the Romanowsky combination. The larger stains less intensely than the smaller, is round, oval, heart-shaped, or

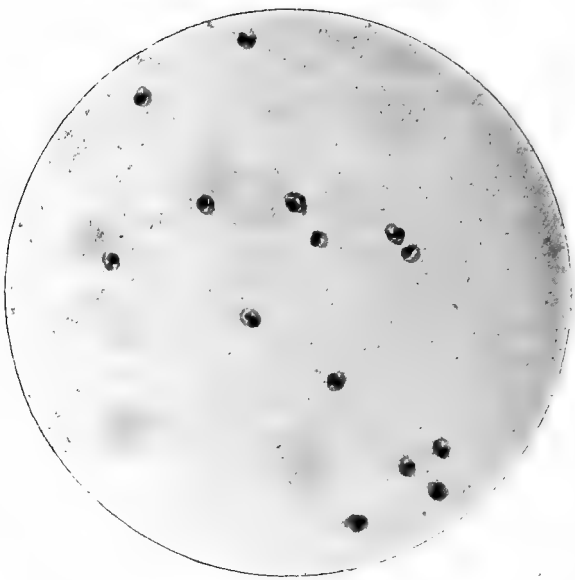

FIG. 198.—Leishman-Donovan bodies from spleen smear. ×1000.

bilobed, and lies rather towards the periphery of the body—in the region of the "hinge" in the cockle-shaped individuals. The other chromatin body is usually rod-shaped, and is set perpendicularly or at a tangent to the larger mass, with which only exceptionally it appears to be connected. Usually the protoplasm contains one or two vacuoles. Though in spleen smears many free bodies are seen, the study of sections shows that ordinarily their position is intracellular,—the cells containing them being of a large mononuclear type (Fig. 199). The view held is that on their entering the circulation they are

taken up by the mononuclear leucocytes and by such cells as the endothelial lining of the splenic sinuses or those lining capillaries or lymphatics, that in these cells multiplication takes place,—it may be to such an extent as to rupture the cell,—and that if thus the bodies become free they are taken up by other cells and the process is repeated. The clusters of bodies sometimes seen in smears are probably held together by the remains of ruptured phagocytes. In capillaries the endothelial cells after phagocyting the bodies probably become detached from the capillary wall, as they are often observed free in the lumen of the vessel—this being well seen in the hepatic capillaries. In the body generally the parasites are found in greatest abundance in the spleen, liver, and bone marrow, and also in mesenteric glands, especially in those draining one of the intestinal ulcers; less frequently they occur in the skin ulcers, and in other parts of the body. Donovan described them as occurring in the peripheral blood, especially within the leucocytes, and this observation has been generally confirmed, though sometimes prolonged search is necessary. Patton has found that the numbers in the blood vary from time to time, and special incursions may be associated with exacerbations of dysenteric symptoms which he holds indicate a spread of the intestinal ulceration.

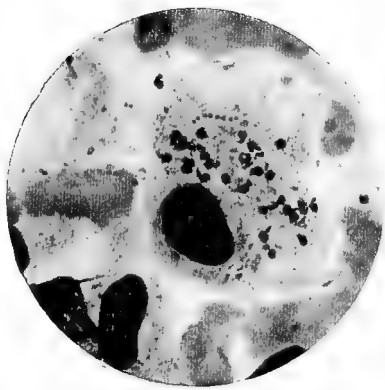

FIG. 199.—Leishman-Donovan bodies within endothelial cell in spleen. See also Plate VI., Fig. 24. ×1000.

In the body the parasite multiplies by simple fission, both nuclei dividing amitotically, and two new individuals being formed; but sometimes a multiple division takes place, each nucleus dividing several times within the protoplasm and a corresponding number of new parasites resulting.

In view of Leishman's original opinion an extremely important discovery was made by Rogers and later confirmed by Leishman himself, to the effect that in cultures a flagellate organism developed from the Leishman-Donovan body. Cultivation was

effected by taking spleen juice containing the parasite, placing it in 10 per cent. sodium citrate solution and keeping it at 17° to 24° C. Under such conditions there occurs an enlargement of the organism, but especially of the larger nucleus. This is followed by the appearance of a pink-staining vacuole in the neighbourhood of the smaller nucleus. Along with these changes, in from twenty-four to forty-eight hours the parasite becomes elongated and the smaller nucleus and its vacuole move to one end; from the vacuole there then appears to develop a red-staining flagellum, which when fully formed seems to take its origin from the neighbourhood of the small nucleus. The body of the parasite is now from 20 to 22 μ long and 3 to 4 μ broad, with the flagellum about 22 μ long. The whole development occupies about ninety-six hours. The formation of an undulating membrane was not observed, and, although the flagellated organism moved flagellum first, like a trypanosome, it is evident that here the relationship of the micronucleus is different, as this structure lies anterior to the macronucleus. In his cultures, which kept alive for four weeks, Leishman made a further important observation the significance of which is still unknown. In certain of the flagellate forms he saw chromatin granules develop in the protoplasm often in couples, a larger and a smaller. There then occurred a very unequal longitudinal division of the protoplasm, and a hair-like undulating individual containing one of the pairs of chromatin granules would be split off. At first these would be non-flagellate, but later a red-staining flagellum would appear at one end; the further development of these spirillary forms could not, however, be traced. The serum of many animals, *e.g.*, man, guinea-pig, has an inhibitory effect on the parasite, but success in the cultivation has attended the use of Novy and MacNeal's medium made up with the serum of the rabbit, sheep, or dog.

The facts just detailed have been the basis for discussion of the classification of the organism, which now usually goes by the name Leishmania donovani, originally given to it by Ross. According to one view, it is to be looked on as a trypanosome; and although, as we have noted, its flagellated form differs from the typical trypanosoma form, it bears considerable resemblance to the members of this group, and, as Leishman has pointed out, his cultures may not represent the full development of the organism in the trypanosoma direction. Others have looked on it as a piroplasma, but Minchin's suggestion has been accepted that in the present incomplete state of knowledge it is well to place it and its congeners in a provisional genus, Leishmania, of the flagellata.

The question arises, given that the Leishmania donovani is the cause of kála-ázar, how is infection spread? On this we have as yet no certain information. Water has been looked on as the carrier of infection, but the possible relationship of the organism to the trypanosomata naturally suggests the idea of an insect as an intermediary, and Rogers adduced some evidence that the bed-bug is the extra-human host. Patton fed the common insect parasites of man in Madras on patients whose peripheral blood contained the Leishmania, and observed the flagellate stage in the bug, *cimex rotundatus*, especially after a single feed with human blood, which, however, as stated above, contains substances inimical to the full development of the parasite. As in all experiments of the kind, difficulties arise in consequence of the great variety of flagellates which normally inhabit the intestine of insects. The fact that the Leishmania may occur only in small numbers in the peripheral blood was advanced as an argument against infection taking place by means of a blood-sucking insect, but often considerable numbers occur in the blood, and, apart from this, invisible spirillary forms may be instruments of infection. It must be stated that up to the present the means by which infection takes place in kála-ázar has not been determined.

Though results obtained in different parts of the world vary somewhat, animals such as the monkey, the dog, and the mouse have, in a proportion of cases, been infected with the parasite as it occurs in human lesions and also in cultures. The intra-peritoneal route is the best, and both when the animals have died and have been killed Leishmaniæ have been found in such situations as the spleen, the liver, the bone marrow. Feeding experiments have usually been unsuccessful, but one or two positive results are recorded. In India the examination of dogs which have been in contact with kála-ázar cases has not yielded evidence that natural infection occurs in these animals.

With regard to kála-ázar as a whole, we may say that we are dealing with a distinct disease fairly widespread in various sub-tropical regions. All attempts to include it among the malarial cachexias, which clinically it so much resembles, have failed. In this atypical cachexial fever there is always present a parasite of very special characters belonging or closely allied to a group which contains many varieties capable of giving rise to similar diseases. Beyond this we cannot go, but there is strong presumptive evidence of the parasite described being the cause of the disease.

Methods of Examination.—The Leishmania donovani can be

readily seen in films or sections of the organs in which we have mentioned its occurrence. These should be stained by the Romanowsky stains. Fluid taken from the enlarged spleen with a perfectly dry needle during life may be examined, but it is probable that in this disease puncture of the spleen may not be a very safe operation, as death from hæmorrhage from this organ is a not uncommon natural terminal event. During life the main points on which a pathological diagnosis may be based are the demonstration of the parasite in the circulating blood, which should always be attempted by means of thick films, the absence of the malarial parasites from the blood, and the features of the leucopenia which have been alluded to.

Leishmania Infantum.—Nicolle, working in Tunis, observed a disease clinically identical with kála-ázar, affecting children between two and five years of age. He found in the spleen, liver, and bone marrow in such cases an organism microscopically indistinguishable from the Leishmania donovani. The disease is very widespread, and occurs along the whole of the south and east littorals of the Mediterranean, in Portugal, Greece, Sicily, and in Italy as far north as Rome, in the Soudan and Abyssinia. The organism can be cultivated on Novy and MacNeal's medium, which was modified by Nicolle as follows :—

Agar carefully washed to remove salts, 14 grms. ; sea salt, 6 grms. ; water, 900 c.c. ; sterilise in autoclave and tube ; melt tubes, cool to 50° C., and add to each one-third of its volume of whole rabbit blood removed aseptically from the heart ; keep tubes in store in dark.

The cultures present characters similar to those observed by Rogers and Leishman in the other Leishmaniæ. It has been found that the organism can be successfully inoculated in the dog, monkey, rabbit, guinea-pig, and rabbit by intrahepatic and intraperitoneal injection of spleen pulp from fatal human cases, and Novy and MacNeal have produced the disease by inoculation with massive doses of cultures. The fact that animals had not, up to the time of his observations, been infected with the Leishmania donovani, and the further fact that the disease, as it occurs in the regions named, is apparently confined to young children, led Nicolle to look upon the organism as a separate species to which he gave the name *Leishmania infantum.* He considered the infection of the dog to be significant, as this animal might be the channel through which children become infected, for in most regions where the disease prevails, there occurs a disease of dogs which may be either of an acute or chronic character, and which is apparently due to an identical

organism. The view has been advanced that infection takes place by the agency of fleas.

Leishmania Tropica.—In various tropical and sub-tropical regions (India, Central Asia and the East, Northern Africa, Southern Russia, Turkey, South America, West Indies) there is widely prevalent a variety of very intractable chronic ulceration which goes by various names in different parts of the world—Delhi sore, tropical ulcer, Aleppo boil, etc. The work of J. H. Wright first showed that a protozoal parasite is concerned in the etiology of the condition. In the discharge from the ulcer and in sections of a portion of tissue excised from a case coming from Armenia, Wright observed great numbers of round or oval, sharply defined bodies, 2 to 4 μ in diameter. When stained by a Romanowsky combination there was found to be a peripheral portion coloured a pale blue and a central portion tending to be unstained; there were also two chromatin bodies, one larger, occupying a fourth or a third of the whole and situated in the periphery, another smaller, round or rod-shaped, and of a deeper colour than the larger mass. It was found that the bodies were usually intracellular in position in the lesion, as many as twenty being in one cell, and that the type of cell containing them was, as in kála-ázar, that derivable from endothelial tissues.

Wright's observations have been fully confirmed by workers in various parts of the world, and it is now recognised that in these tropical ulcers we have a third example of the activity of a Leishmania. Various views have been held as to how infection takes place, but Patton believes the bed-bug to be the intermediate host perhaps exclusively during its nymph stage. The incubation period before the sore develops is about two months, and its duration is about a year. It is stated that after recovery the individual possesses immunity. Sometimes the parasite is destroyed in a foul ulcer, but it can be obtained by taking some of the juice from the marginal indurated tissues by capillary glass tubes. Patton reports having found the organism in the blood taken from parts adjacent to the ulcer. Row has obtained cultures in citrated blood, and Nicolle and Manceaux have reproduced the condition in man, the monkey, and the dog, both by virus obtained from the natural infection and from cultures on Novy and MacNeal's medium. The lesions were identical with those naturally occurring, but the incubation period was often many months. In the male mouse intraperitoneal injection is followed either by a granuloma in the testicle or by a generalised infection in which lesions often characterised by widespread destruction of tissues occur in the skin or around the joints; all

these lesions contain numerous parasites. It may be said that Thompson and Balfour have described in the Soudan a condition in which subcutaneous nodules without ulceration occurred in man, and these contained Leishmania bodies. In South America typical lesions are not uncommon in the nasal mucous membrane, and a similar case has been recorded in the Soudan.

The close similarities in the morphology and effects of the three Leishmaniæ naturally raises the question whether we are not dealing with variants of one organism whose differences depend on differences in the virulence of different types or on the susceptibility of different hosts. The following are some of the facts bearing on the situation: The Indian and Mediterranean diseases are apparently clinically identical, and while on the one hand in certain parts of India kála-ázar is chiefly found in children below the age of fifteen, on the other hand cases occur in young adults in regions where the infantile variety prevails. The importance of such factors as racial susceptibility is indicated by the fact that in Tunis it is chiefly the children of Italian parentage who suffer. Kála-ázar and Oriental sore are linked by the occurrence in the former from time to time of skin ulcers, although in these, unlike the case of Oriental sore, the parasites are difficult to find. Again, Nicolle found that dogs infected with Leishmania tropica appeared to be less susceptible to Leishmania infantum than usual. The incidence of canine Leishmaniosis in communities where a human infection prevails varies in different regions, *e.g.*, even in the Mediterranean littoral, though it is usually common where Leishmania infantum is found. It may be said that the condition of knowledge regarding the inter-relationships of the Leishmaniæ does not permit of any definite opinion being expressed at present. Such an authority as Laveran, however, holds the view that the kála-ázar of India and that of the Mediterranean are identical with each other and with the disease of dogs, and that Oriental sore is a closely allied condition.

Histoplasma capsulatum.—Under this name, Darling has described a parasite observed by him in Panama in a case characterised during life by continued irregular fever, spleno-megaly, emaciation, and anæmia, and *post mortem* showing minute granulomata in the lungs, irregular necrosis and cirrhosis of the liver,—the spleen, naked-eye, resembling that of spleno-myelogenous leukæmia. In smears from the lung nodules, the liver (Fig. 200), and spleen, stained by Leishman's method, there were observed enormous numbers of small bodies sometimes crowding endothelial cells, often free. These bodies were round or oval and from 1 to 4 μ in diameter. Each contained an irregularly placed chromatin mass, the shape of which was globular, oval, or kidney-shaped, the

remainder of the parasite consisting of blue-staining basophilic substance. The parasite is surrounded by a non-staining refractile capsule, one-sixth of the diameter of the parasite in width and sometimes containing a single minute chromatoid dot, and similar granules are sometimes seen in the non-chromatoid part of the body of the parasite. Darling considers this organism to be different from the Leishmania donovani in the form and arrangement of its chromatin and in not possessing a blepharoplast.

Piroplasmosis.

Up to the present no human disease has been proved to be associated with the presence of piroplasmata. But several important diseases of the lower animals are almost certainly caused by protozoan parasites of this group, and a short account of the organisms may be given.

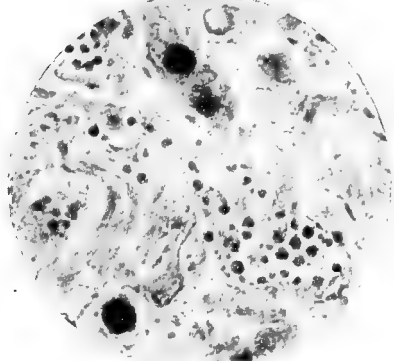

Fig. 200.—Histoplasma capsulatum, section of liver. ×1000.

The piroplasmata are pear-shaped unicellular organisms about 1 to 1·5 μ long and varying in breadth. The peripheral part is denser than the central, which often appears as if vacuolated, and at the broad end there is a well-staining chromatin mass. Sometimes irregular and ring-, rod-, or oval-shaped individuals occur. The organisms are found within the red blood corpuscles of the infected animal and also free in the blood. In the former situation there is sometimes only one within a cell, but the numbers vary under different circumstances and in different species. Multiplication takes place by fission, and the new individuals, remaining for longer or shorter times in apposition, account for some of the appearances seen in cells. Especially in the forms free in the blood, pseudopodial prolongations of the protoplasm, usually from the pointed end, are developed, and it may be by means of such pseudopodia that entrance to the red cells is obtained. Infection is usually carried from infected animals by means of ticks. In one case Koch has described the development in the organism, in the stomach of the tick, of spiked protoplasmic processes sprouting out from the broad end of the piroplasm, and the occurrence of conjugation of two such individuals by their narrow ends to form a zygote. Observations by Christophers indicate that a globular body now appears, probably corresponding to the oöcyst stage of other similar protozoa, and the further development consists in a division into sporoblasts which may infect the whole tissues of the tick, especially the salivary apparatus. The eggs may also be infected, and the young ticks developed from these may thus be capable of carrying the disease to

fresh hosts. Frequently when an animal has passed through an attack of a piroplasmosis it is immune to the disease, and with regard to this immunity in certain cases very interesting facts have been observed. For instance, the condition may not be associated with the disappearance of the parasite from the blood of the immune animal, and the latter may thus be a source of danger to other non-immune animals with which ticks harboured by it may come in contact.

The following are the chief piroplasmata causing disease in animals: (1) *Piroplasma bigeminum.* This was first described by Theobald Smith and is the cause of Texas or red-water fever, a febrile condition associated with hæmoglobinuria, which occurs in the Southern States of America, the Argentine, South and Central Africa, Algeria, various parts of Northern Europe, and in Australia. The organism gets its name of bigeminum from the fact that it is often present in the red cells in pairs, which may be attached to one another by a fine thread of protoplasm; this probably results from the complete separation of two individuals being delayed after division has occurred. Infection is here spread by the tick *boophilus bovis*, and some of the characteristics of the disease epidemiologically are explained by the fact that this insect goes through all its moultings on the same individual host. (2) *Piroplasma parvum.* This organism was discovered by Theiler in the blood of cattle suffering from African East Coast fever, a disease closely resembling Texas fever, which prevails endemically in a narrow strip along a long extent of the east coast, and which occurs epidemically inland. As its designation implies, the organism is small, and it is also attenuated. Its insect host is the tick *rhipicephalus appendiculatus*, and it may be noted that this tick drops off the animal on which it may be feeding when it is about to go through one of its several moultings. It can thus carry an infection much more quickly and widely through a herd than can the carrier of ordinary red-water fever. It may be said that in England there occurs a red-water fever also associated with the presence of a piroplasm in the blood, but the relationship of this organism to the other varieties has not yet been fully worked out. (3) *Piroplasma equi.* This organism gives rise to biliary fever in horses, another South African disease, and it is carried by the tick *rhipicephalus evertsii.* In this disease Theiler made the interesting observation that when the blood of a donkey which had recovered from the disease was injected into a horse, the latter suffered a slight illness only, although the organisms were present in the blood injected. Such a fact is of importance, as attenuation of virulence in pathogenic protozoa seems, so far as our present knowledge goes, a not very common event. (4) *Piroplasma canis.* This causes a piroplasmosis occurring in dogs.

With regard to the pathology of infection by piroplasmata we know nothing. The diseases are often extremely fatal, carrying off nearly every individual attacked, but we do not know the nature of the changes originated.

APPENDIX F.

YELLOW FEVER.

YELLOW fever is an infectious disease which is endemic in the West Indies, in Brazil, in Sierra Leone and the adjacent parts of West Africa, though it is probable that it was from the first-named region that the others were originally infected. From time to time serious outbreaks take place, during which neighbouring countries also suffer, and the disease may be carried to other parts of the world. In this way epidemics have arisen in the United States and elsewhere, infection usually being carried by cases occurring among the crews of ships. In the parts where it is endemic, though usually a few cases may occur from time to time, there is some evidence that occasionally the disease may remain in abeyance for many years and then originate *de novo*. There is, therefore, reason to suspect that the infective agent can exist for considerable periods outside the human body. It is possible, however, that continuity may be maintained by the persistence of a mild type of the disease, which may be grouped with the "bilious fevers" prevalent in yellow fever regions, and some writers even speak of "carriers" of the virus. This would explain the degree of immunity which is shown during a serious epidemic by the older inhabitants.

Great variations are observed in the clinical types under which the disease presents itself. Usually after from two to six days' incubation a sudden onset in the form of a rigor occurs. The temperature rises to 104–105° F. The person is livid, with outstanding bloodshot eyes. There are present great prostration, pain in the back, and vomiting, at first of mucus, later of bile. The urine is diminished and contains albumin. About the fifth day an apparent improvement takes place, and this may lead on to recovery. Frequently, however, the remission, which may last from a few hours to two days, is followed by an aggravation of all the symptoms. The temperature rises,

jaundice is observed, hæmorrhages occur from all the mucous surfaces, causing, in the case of the stomach, the "black vomit"—one of the clinical signs of the disease in its worst form. Anuria, coma, and cardiac collapse usher in a fatal issue. The mortality varies in different epidemics from about 35 to 99 per cent. of those attacked. Both white and black races are susceptible, but those who have resided long in a country are less susceptible than new immigrants. An attack of the disease usually confers complete immunity against subsequent infection.

Post mortem the stomach is found in a state of acute gastritis, and contains much altered blood derived from hæmorrhages which have occurred in the mucous and sub-mucous coats. The intestine may be normal, but is often congested and may be ulcerated; the mesenteric glands are enlarged. The liver is in a state of fatty degeneration of greater or less degree, but often resembling the condition found in phosphorus poisoning. The kidneys are in a state of intense glomerulo-nephritis, with fatty degeneration of the epithelium. There is congestion of the meninges, especially in the lumbar region, and hæmorrhages may occur. The other organs do not show much change, though small hæmorrhages under the skin and into all the tissues of the body are not infrequent. In the blood a feature is the excess of urea present, amounting, it may be, to nearly 4 per cent.

Etiology of Yellow Fever.—Although in earlier days a large amount of bacteriological work was done on yellow fever, this has merely a historical interest, as it is now known that the causal agent is not one of the ordinary bacteria, but belongs to the group of ultra-microscopic organisms.[1] A mosquito acts as the intermediate host, and the facts detailed below point to the organism passing through some cycle of development in the body of the insect. The analogy of malaria makes it extremely probable that the organism is a protozoon, but this has not yet been completely proved. As bacteriological work led up to the establishment of our knowledge regarding the nature of the disease, some reference must be made to it.

A very full research into the bacteriology of yellow fever was that of Sternberg, and one of the organisms isolated, which he called the bacillus *x*, appeared possibly to have some relationship to the disease. Sanarelli in 1897 isolated an organism which he

[1] As has been stated in dealing with smallpox and rabies, in several diseases the existence of such causal factors is probable. Examples in animals are foot-and-mouth disease, South African horse sickness, and the contagious pleuro-pneumonia of cattle.

called bacillus icteroides, and which he considered to be the cause of yellow fever; it was probably identical with the bacillus *x* of Sternberg, but subsequent observations made by others gave conflicting results. The bacillus icteroides, as described by Sanarelli, belongs to the paratyphoid group, possessing lateral flagella growing on gelatin without liquefaction, and fermenting glucose but not lactose. Reed and Carroll found that it was practically identical with the bacillus of swine cholera. It must now be considered merely as an organism which may occur in the organs and tissues in yellow fever as a secondary infection, but without any etiological significance.

The facts of importance which have been established regarding the etiology of the disease are due to the labours of the United States Army Commission, which began its work in 1900. The members of the Commission first directed their inquiries towards determining whether the bacillus icteroides was present in the blood during life, and a series of cases was investigated bacteriologically, with entirely negative results in each instance. They then resolved to test the hypothesis of Dr. Carlos Finlay of Havana, promulgated several years previously, that the disease was carried by mosquitoes. Selecting mosquitoes which they had reared from eggs, they allowed them to bite yellow fever patients and then to bite healthy men. Of several experiments of this nature two were successful in the first instance, the first individual to be infected in this way being Dr. James Carroll, a member of the Commission, who passed through a severe attack of typical yellow fever. Experiments were then performed on a larger scale, with completely confirmatory results as to the conveyance of the disease by mosquitoes. Of twelve non-immunes living under circumstances which excluded natural means of infection, ten contracted yellow fever after having been bitten by mosquitoes which had previously bitten yellow fever patients; happily all of these recovered. Two of the men who were thus infected had been previously exposed to contact with fomites from yellow fever patients without results. These results were confirmed by Guitéras, whose investigations were carried out along similar lines; of seventeen individuals bitten by infected mosquitoes, eight took yellow fever, and three of these died.

The species of mosquito used by the American Commission was the *Stegomyia fasciata*, and up to the present time no other species has been found capable of carrying the infection. It has also been determined that a certain period must elapse after the insect has bitten a yellow fever patient before it becomes infec-

tive to another subject. In summer weather this period is about twelve days; at a lower temperature somewhat longer. This probably means that, as in the case of malaria, the parasite must pass through certain stages of development before it reaches the salivary gland and is thus in a position to be transferred to a fresh subject. Infected mosquitoes, however, retain the power of infection for a considerable time afterwards, probably as long as sixty days. It has also been shown that mosquitoes may become infective after biting a patient on the first, second, or third day of the disease, but at a later period the results are usually negative, apparently because the virus is no longer present in the blood.

Interesting results were also obtained with regard to the communication of the disease directly from patient to patient, the conclusion arrived at, after careful experiments, being that the disease cannot be transferred in this way, even when the contact is of a close character. In a specially constructed house seven men were exposed to the most intimate contact with the fomites of yellow fever patients for a period of twenty days each, the soiled garments worn by the patients being in some cases actually slept in by these men; the result was that not one of those thus exposed contracted the disease. The conclusions on this point have been subsequently confirmed by other workers.

The American Commission also found it possible to transmit yellow fever to a healthy man by injecting small quantities of blood or of serum taken from a yellow fever patient at any period up till the third day of the disease. The period of incubation in this case is somewhat shorter than when the disease is conveyed by the bite of mosquitoes, the average duration in the former case being about three days, and in the latter about four days, though these times may be considerably exceeded. It is also interesting to know that in these experimental injections the blood or serum used was found to be free from bacteria. Up till the present time, we know of only these two methods of infection, namely, indirectly by the bite of a mosquito infected with the yellow fever germ; or directly by the injection of some of the blood from a yellow fever patient. In these respects there is a striking similarity to what has been established in the case of malarial fever.

Experiments with regard to the nature of the yellow fever organism were carried out by Reed and Carroll, and interesting results were obtained. They found that the organism of the disease was very easily killed by heat, as blood from a yellow fever patient lost its infective power on being heated to 55° C.

for ten minutes. On the other hand, blood or serum was found to be still infective after having been passed through a Berkefeld filter. This was confirmed by the French Commission, with the additional result that the virus passes through a Chamberland F filter, but not through a Chamberland B. These facts would show that the parasite is of extremely minute size, and apparently belongs to the group of ultra-microscopic organisms. In accordance with this, attempts to find by microscopic examination the yellow fever parasite, either in the blood of patients suffering from the disease or in the tissues of infective mosquitoes, have been attended with negative results. In 1912, however, Seidelin described the presence in the blood of a minute intracorpuscular parasite resembling a piroplasma: it was found both in the erythrocytes and in the leucocytes. He regards it as a new genus, to which he has given the name *paraplasma flavigenum*, and believes that it is the causal organism. Although he found it in a large proportion of cases of the disease, his results have not yet been confirmed by others. It has been stated that it is possible to produce yellow fever in the chimpanzee by the injection of blood from a patient.

Though nothing has been determined regarding the actual nature of the virus, yet the results already obtained have supplied the basis for preventive measures against the disease, these being directed towards the destruction of mosquitoes and the protection of those suffering from yellow fever, and also the healthy, against the bites of these insects. Already a striking degree of success has been obtained in Havana. Such measures came into force in February 1901, and in ninety days the town was free of yellow fever, and for fifty-four days later no new cases occurred; and although subsequently the disease was reintroduced into the town, no difficulty was experienced in stamping it out by the same measures. In recent years the results have also been highly gratifying, and the disease may be said to be practically eradicated from Havana. In other large centres of population, for example Rio de Janeiro, equally successful results have been obtained, and epidemics in limited areas would appear to be now under control if the proper measures are taken. In striking contrast to this is the fact that in certain places where preventive measures have not yet been satisfactorily instituted, owing to the population being scattered or other causes, the mortality from yellow fever still remains high.

APPENDIX G.

EPIDEMIC POLIOMYELITIS.

WHILE the occurrence of "infantile paralysis" of sudden onset, and affecting especially one or more limbs, has been known since the earliest times, it is only coincident with the modern developments of neurology that the most prevalent type has been recognised to be associated with inflammatory changes which are specially concentrated in the anterior cornua of the spinal cord. Though the disease chiefly attacks children, older subjects are also affected, and in some epidemics the infection of adults is a prominent feature. The disease is usually sporadic in its incidence, and, as has long been known, in temperate climates it is of most frequent occurrence during the warmer months of the year. It also occurs in an epidemic form. Such outbreaks have been familiar in Norway and Sweden during the last century, but in other countries similar epidemics, limited or extensive, have come under notice. Thus in New York in the summer of 1907 an outbreak of probably over 2000 cases occurred, 762 of which were carefully investigated by a special Commission, and it is from their work that much of our present knowledge of the disease has been derived, and many facts regarding its infective nature have been definitely established. An even more serious epidemic took place in New York in 1916. Clinically, the onset of the condition is marked by more or less pronounced fever, often accompanied by sore throat and followed after a few days by signs of paresis and paralysis, and usually in a relatively small proportion of cases resulting in death, though there is great variation in the mortality in different outbreaks. When recovery occurs, many of the paralytic symptoms may pass off, but generally there remains evidence of definite permanent injury to the motor functions of the nervous system. Pathologically, the initial lesions consist in a local or general leptomeningitis with pronounced leucocytic exudation of a polymorpho-nuclear type into the perivascular

lymphatics, the existence of which is reflected in the appearance of such cells in moderate numbers in the cerebro-spinal fluid. In the cord the inflammatory condition is usually marked in the arterioles of the anterior commissure, especially in the cervical and lumbar regions, and thence passes into the anterior cornua along the vessels, which show intense hyperæmia with perivascular cell proliferation and which may become thrombosed or rupture. The nutrition of the grey matter is thus interfered with, the nerve cells may die and become the prey of neuronophages, and secondary local and systemic degenerations may follow. Such a pathological picture, however, is not confined to the grey matter nor indeed to the cord, as similar changes have been observed in the brain. The recognition of this has widened the whole conception of the disease, and various clinical types besides the classic anterior poliomyelitis are now recognised to exist. These depend partly on variations in the severity of the condition, partly on the fact of the disease being concentrated in a particular part of the nervous system. These less common types probably include many cases described as the acute ascending paralysis of Landry, acute bulbar paralysis, cases characterised by acute meningitis or encephalitis, cases of rapidly developing ataxia, and even cases simulating neuritis.

The infectivity of the disease was established by the work of Landsteiner and Popper, who in 1909 in Vienna succeeded in producing the disease in a monkey by the intraperitoneal injection of an emulsion of the spinal cord of a child who had succumbed on the fourth day of illness. Similar observations were made in the same year by Flexner in New York, who found that if for intraperitoneal injection intracerebral inoculation was substituted, disease results were more uniformly produced, and the brain and cord of the infected animals were infective for other monkeys, the incubation period being from 4 to 33 days. It is on the work of Landsteiner, Levaditi, and especially of Flexner that our present knowledge is chiefly based. Hitherto the monkey is the only animal to which the disease has certainly been communicated,—both the anthropoid apes and the lower monkeys are susceptible, and the conditions resulting from inoculation are clinically and pathologically identical with those observed in man.

With regard to the nature of the virus the discovery was made independently by Flexner and Lewis, and by Landsteiner and Levaditi, that it could pass through an earthenware filter (*e.g.*, Berkefeld N or V). The deduction from this observation was that the causal organism must be very small, and Flexner

and Noguchi succeeded in cultivating minute bodies which there is reason to suppose are the infective agent. In their experiments, small portions of the central nervous system,—preferably the brain,—removed *post mortem*, were inserted in a medium composed of naturally sterile ascitic fluid containing a fragment of sterile fresh rabbit kidney, and the cultures incubated at 37° C. under anaerobic conditions. About the fifth day faint opalescence appeared, and the fluid was found, when treated with the Giemsa stain, to contain minute bluish or violet globoid bodies, about 0·2 μ in diameter, in pairs, chains, or, less commonly, in groups. Towards Gram's stain their behaviour was variable. It was found that similar cultures could be raised from the infective filtrates. Further, the organism could adapt itself to other media and could be maintained in subculture. By inoculating monkeys with these cultures, under precautions which excluded the possibility of infections being derived from the brain matter originally used, poliomyelitis was set up in the animals, and the organism was recovered from their brains. The "globoid bodies" (whose nature is unknown) were also microscopically demonstrated, by means of the Giemsa stain,[1] in the brain in both the natural and experimental disease.

In infecting monkeys from a human case it is advisable to commence with the use of an emulsion of the central nervous system, for filtered emulsions possess much less virulence; but after a few *passages* through monkeys it is found that filtration has little effect in diminishing the number of successful inoculations, the virus being now so potent that 0·001 to 0·01 c.c. of an emulsion of material from the central nervous system (p. 690) in distilled water will originate the disease when injected into the brain. Such a virus withstands glycerination for years and can be kept frozen at $-2°$ to $-4°$ C. without being affected. It also withstands from 1 to 1½ per cent. phenol for at least five days; it is, however, killed by an exposure at 45° to 50° C. for half an hour. The disease can be originated by subdural and intracerebral injection, and also by introduction into the sheath of such a nerve as the sciatic. When the sheath of a nerve is infected, the paralytic symptoms usually first appear in relation to that part of the cord from which the nerve emerges. Infection can also readily be produced by scarifying the mucous membrane of the nose and rubbing the virus into it, or even by simply injecting it into the nasal cavities. The intraperitoneal, intrathecal, and subcutaneous routes can also

[1] See Flexner and Noguchi, *Journ. Exp. Med.* (1913), xviii. p. 461.

be employed, but to cause the disease by intravenous injection enormous doses must be administered. By means of the inoculation method the distribution of the virus in the natural and experimental disease has been determined and has been found to be similar in both cases. The virus is markedly neurotropic and is highly concentrated in the brain and spinal cord. It also occurs in the intervertebral ganglia, the Gasserian ganglion, and in the abdominal sympathetic ganglia. It may be found in the lymphatic glands, especially the tonsil and those of the mesentery, and it has been demonstrated in the nasal mucous membrane. It is absent from the solid organs, the blood, and the cerebro-spinal fluid.

Flexner's view of the pathology of the disease is that infection takes place through the nasal mucous membrane, a catarrh of the buccal and nasal cavities being often the first sign of the disease. In monkeys in which intracerebral inoculation has been practised the virus is eliminated into the nose, and the nasal mucus has been found to be infective in human cases. When an individual is infected by the inhalation of such mucus it is probable that the virus gains access to the brain by the lymphatics of the olfactory nerves; this view rests on the observation that when monkeys are inoculated by painting the infective material on the nasal mucosa, the olfactory lobe becomes infected before other parts of the brain. This fact, as well as the size of the dose required to produce infection by intravenous injection, militates against the possibility of the virus being carried to the central nervous system by means of the blood under natural conditions. There is evidence from experimental intravenous injections that the choroid plexus, which is the source of the cerebro-spinal fluid, prevents (so long as it is uninjured, *e.g.*, by inflammation) the passage of virus into the subdural space. It is likewise possible that in natural infection the virus may pass into the mesenteric nodes and thence be absorbed by the lymphatics of the spinal nerves. All the facts point to the importance of the part played by the peri- and intra-neural lymphatics in the causal agent gaining access to the central nervous system. While the virus may be said to be neurotropic, the term must be used in the sense that all the elements of the nervous system—pia-arachnoid, glia, interstitial blood vessels as well as parenchymatous cells—show a special susceptibility. The pathological anatomy in these structures has been described above.

These observations have furnished important indications of the method by which infection takes place, and by which both the sporadic cases and the epidemic outbreaks occur. It

has been found that in monkeys recovered from the disease, the nasal mucosa remains infective for many months after the virus has disappeared from the central nervous system, and it has been established that in man there are chronic carriers such as exist in other diseases. As in other conditions, the carrier may not himself suffer from the effects of the infective agent which he carries. Further, the occurrence of abortive cases may constitute a means by which infection is maintained in a community. Such abortive cases are probably fairly common during epidemics. In connection with this aspect of the subject, Amoss and Taylor have made the interesting observation that in some individuals the normal nasal secretion possesses a certain power of neutralising the poliomyelitic virus. Finally, it is to be noted that there is a periodicity in the incidence of poliomyelitis in an epidemic form. As bearing on the explanation of this, Flexner, Clark, and Amoss record the case of one strain of the virus the virulence of which in monkeys was at first low, and then rose to a maximum which was maintained for three years; this phase was succeeded by a decrease in infectivity in a few months, without apparent cause. It is obvious that this fact is not only of importance in relation to poliomyelitis, but is suggestive as bearing on the periodicity of other epidemic diseases.

Some workers differ from Flexner on certain points regarding the pathology of poliomyelitis. Thus Rosenow and Towne look on the "globoid bodies" as specially small forms of a rather large streptococcus which they have isolated from the brain in both the natural and experimental disease,—which can grow under aerobic conditions and can produce poliomyelitis, not only in monkeys but also in rabbits. These organisms have been found in certain cases by other observers, who, however, deny that the disease conditions they produce are to be classified with poliomyelitis. Another point on which difference of opinion has arisen is regarding the mode of spread of the disease. Rosenau has put forward observations pointing to a blood-sucking fly, *stomoxys calcitrans*, being capable of transferring the disease in monkeys. As the worst epidemics of poliomyelitis occur in summer, the possibility of an insect carrier has thus been entertained. The absence of the virus from the blood in man, and the difficulty of originating the disease by intravenous injection, are facts militating against such a theory, which, it must be held, has not yet been established.

Though no cases are recorded of a second attack of poliomyelitis in man, our knowledge regarding immunity is mainly derived

from animal experimentation. Monkeys which have passed through an attack of the disease are insusceptible to fresh inoculation, but definite disease manifestations are apparently essential to the establishment of immunity, as animals which have at first yielded negative results are usually susceptible to a second inoculation. Both in man and in the monkey the serum of a recovered case contains substances capable of neutralising the virus, for if such serum be mixed with virus and incubated for a time at 37° C. the mixture becomes inoperative on intracerebral injection into monkeys. The antibodies persist in the serum in man for many years after an acute attack, and they possess this further significance, that they may be found in the so-called abortive cases where a transient illness with little or no involvement of the nervous system occurs. The only evidence, in fact, that such a condition is due to the virus of poliomyelitis lies in the fact that subsequently the serum has the capacity of neutralising the virus. Not only has the immune serum neutralising properties *in vitro*, but it has been shown experimentally to have a certain effect *in vivo* when introduced intrathecally into monkeys previous to intravenous inoculation. Here it probably neutralises the virus as the latter is passing through the cerebro-spinal fluid. Further, the serum of recently recovered human cases when injected into patients suffering from poliomyelitis (especially during the first forty-eight hours) has a capacity of arresting paralysis. The amount of serum given has been from 35 to 120 c.c., administered both intrathecally and intravenously. It is stated by Kraus that if the virus which has been killed by exposure to phenol is injected into monkeys they develop resistance, but such a prophylactic vaccine treatment requires further investigation.

The fact that poliomyelitis appears under a variety of clinical types makes the diagnosis difficult in many cases, especially of mild illness. This is specially true of the meningitic type, which may be difficult to distinguish from epidemic cerebro-spinal meningitis, especially as the characters of lumbar puncture fluid in the two diseases are very similar, and, as is known, it may often be difficult to isolate the meningococcus where it is actually the causal organism. It may be stated that cases have occurred where the diagnosis lay between poliomyelitis and the paralytic type of rabies, and in the present stage of knowledge the susceptibility of the rabbit to the latter disease would constitute the only means by which the diagnosis could be arrived at.

Römer has described a paralytic disease in guinea-pigs closely resembling human poliomyelitis.

Epidemic Encephalitis.—During the spring and summer of 1918 a number of cases of encephalitis occurred in Britain, whose nature has not been satisfactorily elucidated. They were characterised clinically by lethargy and drowsiness, often passing into coma, with moderate or no rise of temperature. A great variety of nervous symptoms were recorded,—headache, epileptic fits, spastic phenomena, ascending paralysis, etc.,—but the most common and striking feature was the existence of irritative and paralytic affections of the muscles of the eyelids and eyeballs. The mortality was high. In fatal cases the chief post-mortem changes were, small sub-pial hæmorrhages and hæmorrhages into the grey and white matter of the brain. There was sometimes marked subdural œdema. Meningitis was not a marked feature, and when it occurred, was patchy; the cerebro-spinal fluid was usually clear. Microscopically, the hæmorrhages appeared to be of venous origin, there was intense capillary congestion and moderate peri-adventitial cellular infiltration; degenerative changes in the oculo-motor centres were recorded. The occurrence of ophthalmoplegia suggested that the condition was botulismus, but the symptoms of the two diseases did not otherwise correspond. No association with the taking of particular articles of food was traceable, and, so far as we are aware, the b. botulinus was never isolated from any of the cases. It was also suggested that the condition was poliomyelitis of an aberrant type, but the findings differed in certain respects from those of the cerebral cases which have been observed during epidemics of poliomyelitis, and, further, there was no evidence of a concurrent prevalence in Britain of ordinary poliomyelitis. The condition was not confined to Britain, an outbreak having been recorded in Austria during 1917, and in France in 1918; and an obscure disease of a similar nature, which however may have been poliomyelitis, occurred in 1917 in Australia. In the British cases the bacteriological findings were as a rule negative, but in Austria a streptococcus is said to have been isolated which reproduced the disease in monkeys. At present no opinion as to the essential pathology of the condition can be formed, but, on the whole, the evidence rather points to this form of encephalitis not being identifiable with poliomyelitis. It may be said that before poliomyelitis had been recognised as a specific entity, Wernicke (1881) described the above type of disease under the name *encephalitis acuta hæmorrhagica.*

Methods.—The inoculation of a monkey constitutes the only certain means of diagnosis in a doubtful case of poliomyelitis. A piece of brain removed with all aseptic precaution from a

fatal case is ground up with sand and saline (the brain tissue forming 5 per cent. of the whole). The product is centrifuged, and the supernatant fluid, filtered through paper, is used for the inoculation. Portions of the central nervous system may be placed in glycerin when transmission to a laboratory is necessary. In certain cases information might be obtained by inoculating material from swabs of sterile wool allowed to remain in the nasal passages, in order that the mucus may be absorbed. Portions of tissue removed from the tonsils might also be useful; in each case the material may again be immersed in small quantities of glycerin, or advantage may be taken of the fact that the virus can survive exposure to 1 per cent. phenol for several days.

APPENDIX H.

PHLEBOTOMUS FEVER.

In Dalmatia, Herzegovina, and neighbouring parts of the Adriatic littoral there occurs a disease known as "pappataci," characterised by fever lasting for about three days, followed by somewhat prolonged prostration, but very rarely having a fatal issue. Doerr, after failing to isolate any organism from the blood, found that the subcutaneous injection of from 0·5 to 1 c.c. of the serum from a case into a healthy individual was followed about eight days later by an attack of the disease. A similar effect was produced with the serum after it had been passed through a Berkefeld filter,—all the inoculation experiments being performed at a distance from the original location of the disease. The view is therefore put forward that here we have to deal with another example of an ultra-microscopic virus. The disease has been only observed in the summer season, and Doerr considered there was justification for the popular view that it was associated with the bite of the dipterous fly, *phlebotomus pappatasii*. This was borne out by the fact that on feeding such flies on a sick person, transporting them to a locality free from the disease and allowing them to bite healthy individuals, the affection was reproduced. An apparently identical disease occurs in Malta, and has been investigated by Birt under the name of "Phlebotomus Fever." This observer fully confirmed Doerr's results, the condition again being reproduced by infected flies, which, however, were found not to manifest infectivity earlier than seven days after biting. This last fact would indicate that the causal organism passes through a developmental cycle in the fly. The disease also occurs in Northern Africa, in Corsica, in Calabria, and probably generally throughout Italy, in Portugal, and in Arabia.

These results are of importance themselves, as throwing light on the etiology of a troublesome disease of the Mediterranean littoral, but they are also interesting as having a possible

bearing on the pathology of a group of similar affections occurring in various parts of the world,—chiefly in coastal areas,—and going under a variety of names. Examples are dengue, the three-day fever of various regions, Canary fever, Shanghai fever, Chitral fever, and the seven-day fever or simple continued fever of India. Of these, that presenting the most definite clinical picture is dengue,—a condition for long well known and having an extensive distribution, and it may be said that Ashburn and Craig in the Philippines found the blood in dengue as in pappataci to be infective even after filtration, the insect host however, being *culex fatigans*. Whether all these disease conditions are identical, further research must decide; at present Birt believes that at any rate pappataci and dengue are distinct, and certainly Doerr does not in his description allude to the terminal skin eruption which Manson believes to be of very constant occurrence in the latter. The rarity of a fatal result in these diseases makes their investigation by inoculation of the human subject relatively safe.

APPENDIX J.

TYPHUS FEVER.

ALL attempts to elucidate the etiology of this disease by ordinary bacteriological methods had given equivocal results till Nicolle initiated research on the subject in Tunis in 1909. This observer found that the blood of cases of typhus fever during the pre-febrile, febrile, and immediately post-febrile periods was infective for both the higher and lower monkeys, in the latter especially when introduced intraperitoneally. An illness, frequently fatal and practically identical with the disease in man (including the skin eruption), is originated, and the blood of affected animals is again infective towards fresh individuals. A large number of such passages were successfully practised. The only other animal susceptible to similar infection appears to be the guinea-pig, in which there arises an illness after eight to eleven days' incubation, characterised by fever and loss of weight; the illness lasts from four to seven days and is only exceptionally fatal. The virus is present in the blood during the illness in the guinea-pig, and also exists in the solid organs. In this animal likewise it can be maintained by passage. The most important fact established by Nicolle was that infection takes place through the *pediculus vestimenti*. Monkeys and guinea-pigs can both be infected by the bites of lice previously fed on a human case. There is evidence that the causal organism undergoes some developmental stage in the intermediate host, as the bite of the louse is specially infective from the fifth to the seventh day after feeding. During the present war there have been serious outbreaks of typhus fever in Serbia, Bulgaria, and Poland, and sanitary measures founded on the view that the body louse is essential to the spread of the epidemic have met with success. It has been known that children under ten years are, apparently, less susceptible to typhus than older individuals, and Nicolle made the interesting observation that when a family is attacked, young children, while apparently

well, may really suffer from a slight rise of temperature. This condition is probably an abortive attack of the fever, as the blood in such cases is infective for monkeys. These abortive cases may play a part in the dissemination of an epidemic, and also, it is possible, in the recurrent outbreaks of the disease in cities in which otherwise there is no evidence of typhus fever being endemic in its usual form. Nicolle's results have been confirmed in America by Anderson and Goldberger and by Ricketts and Wilder. These observers in the first instance were dealing with a fever in Mexico known as *tabardillo*. Anderson and Goldberger, however, also worked with cases of a disease occurring in New York (described by Brill), which were undoubtedly a mild type of typhus fever imported from Europe, and they proved experimentally the identity of the two conditions. Nicolle observed that as in the case of man, when an experimental animal passes successfully through an attack of the disease it becomes immune. Although the serum of both men and animals during convalescence possesses slight viricidal properties, this rapidly disappears. Nicolle and Blaizot by immunising the horse with bruised supra-renals and spleens of infected guinea-pigs have produced a serum which has protective and curative effects in man. On the other hand, Blanc used the infected guinea-pig's blood sterilised at 55° C. as a prophylactic and therapeutic vaccine.

Nicolle has not advanced any views with regard to the nature of this infective agent beyond the fact that it is destroyed by a short exposure at from 50° to 55° C. He adduced some observations pointing to its being filterable, but these have not been confirmed. Ricketts and Wilde described in the blood of typhus patients minute rod-shaped bodies with polar staining. This observation has been confirmed, especially in lice, by Prowazek, Rocha-Lima, Topfer, and Schussler and others. The bodies vary in size, the smallest being cocciform and less than the m. melitensis, or elliptical, with one end pointed; larger forms also occur,—rod-shaped, with polar staining and an unstained central part,—some say the ends are surrounded by a pale capsule. In the louse they may occur amongst the débris of red blood cells in the stomach, but are most marked in the epithelial cells of the stomach and intestine, and in the salivary glands. According to present results, like appearances have not been found in control lice which have not been fed on typhus patients. Notwithstanding their likeness to coccobacilli, Rocha-Lima inclines to look on these bodies as protozoa, and suggests for them the name *Rickettsia prowazeki*. There is general

agreement that ordinary cultural methods applied to typhus blood yield no result, but lately some attention has been attracted to the isolation by Plotz of a gram-positive anaerobic bacillus (b. typhi exanthematici) which Olitzky and others have also cultivated from infected lice. Further, a proteus-like bacillus has been isolated from the urine in typhus fever, and though there is no evidence that this organism has any causal relationship to the disease, several observers have confirmed the observation that it is agglutinated by the serum of typhus patients up to 1 to 1500,—this being known as the Weil-Felix reaction.

Rocky Mountain Fever.—This is a typhus-like disease which has been the subject of much investigation in America. The essential pathological anatomy appears to be an inflammatory reaction of the adventitia of the vessels of the subcutaneous tissue and of the genitalia, with degenerative changes in the media, and a perivascular monocellular reaction. There is also thrombosis in the vessels. There is evidence that the disease is transmitted by a tick, *dermacentor andersoni.* Monkeys and guinea-pigs can be infected with the blood, and also by ticks. In the guinea-pig the illness is much more severe and fatal than in typhus infection. There is fever with, in the male, swelling and hæmorrhage of the scrotum, swelling and rash in the ears, and swelling and it may be necrosis of the paws. In the vessels in human cases and in infected guinea-pigs, and also in the stomach of the tick, Wolbach has found bodies 0·5 to 1 μ long, and 0·2 to 0·5 μ broad, which closely resemble the *Rickettsia prowazeki.* According to Cumming the disease can be distinguished from typhus by the reaction in the guinea-pig.

APPENDIX K.

TRENCH FEVER.

Trench fever has been recognised as a distinct disease only during the present war, and quite recently it has been shown to be a louse-borne infection. Though not a fatal malady, it has been responsible, owing to its wide prevalence, for a serious amount of temporary disablement in the armies, while the after-effects, which occur in a certain proportion of cases, have been the cause of much chronic ill-health. The onset of the disease is usually sudden, and, along with pyrexia, the chief symptoms are headache, giddiness, and pains in the legs, in the back, and behind the eyes. The face is flushed and the conjunctivæ are often congested; free perspiration is present, also polyuria and a tendency to constipation. There is moderate leucocytosis during the pyrexia, punctate basophilia of the red corpuscles is a common feature, and the spleen is often found to be swollen. No other distinct morbid changes have been found. The temperature curve is on the whole somewhat irregular, though it sometimes assumes a regular relapsing character. The initial attack of marked fever, which may show fluctuations, lasts usually three to six days; thereafter the temperature falls to normal and the symptoms subside. In many cases there occurs three or four days later a distinct relapse of shorter duration and less severity than the original attack, or there may be slight irregular pyrexia. In other cases, constituting a minority, a regular relapsing type of fever supervenes, the temperature rising sometimes to 104° C. and falling to normal again within two days; whilst there are intervals of about five to seven days between the attacks, during which fever and other symptoms are absent. This type of fever may occur at the beginning of the disease, or, on the other hand, may develop weeks after the primary attack. Whilst in the majority of cases complete recovery occurs within a comparatively short time, patients who have had trench fever may suffer at a later stage from myalgia and rheumatic pains, irregu-

lar action of the heart, and a tendency to slight febrile attacks, and may become chronically disabled.

Extensive observations carried out on this affection failed to show the presence of any bacterium. The first important step in the elucidation of its pathology was made by M'Nee and Renshaw, who showed that the disease could be transmitted to a healthy individual by the intramuscular or intravenous injection of the blood of a patient in the acute stage. In these experiments the period of incubation varied considerably, namely, from six to twenty-two days. They found also that the disease was not transmissible by the separated serum, whereas the red corpuscles repeatedly washed in saline were still infective. They accordingly concluded that the infective agent was an intra-corpuscular parasite which could not be demonstrated by microscopic methods.

It has recently been shown by the independent investigations of a British War Office Committee working in this country and an American Research Committee in France, that trench fever is transmitted by means of lice, the first actual publication of positive results being made by the British Committee in March 1918. The results of the two committees are in close agreement, the chief point of difference being as to the exact mechanism by which the louse produces the infection. The British Committee made numerous attempts to transmit the disease by the bites of lice which had previously fed on trench fever patients, but without success. If, however, the excreta of such lice were collected and dried, and inoculation with the excreta was then made by scarification of the skin of healthy men, they found that trench fever resulted in a considerable number of cases, the period of incubation being on an average about eight days. After lice are allowed to feed on a trench fever patient, a period of five days at least elapses before their fæces become infective, this period suggesting a cycle of development in the louse, or indicating the time during which the organisms multiply sufficiently to produce infection. The lice remain infective for a period of at least twenty-three days after being infected. It was also found that the bodies of infected lice when crushed on the broken skin are capable of giving rise to trench fever. Even as late as eleven weeks after the onset of the disease the blood during a febrile attack may contain the organism of the disease, as was shown by its capacity of infecting lice—a fact in accordance with the protracted character of the disease in some cases and the recrudescence of typical symptoms. It was found impossible to produce infection by the excreta of

healthy lice—that is, the virus is not normally resident in the insect. Further, the infective agent is not transmitted from infected lice to their offspring. The comparative regularity with which the disease may be produced in men of various ages by infected lice, shows that the proportion of naturally immune individuals is very small.

The American Committee were able in a considerable number of cases to produce infection by simply transferring to healthy individuals lice which had fed on trench fever patients some time previously, the period of incubation being fourteen to thirty-eight days. And in five experiments where means were taken to exclude any other method of infection than the direct bite of the insects, positive results were obtained in all, after a corresponding period of incubation. On the other hand, when infection was by scarification with excrement, they found that, as stated above, the incubation period is much shorter. Their results agree with those mentioned as to a period of several days elapsing before the lice become infective after biting a patient suffering from the disease.

Both committees confirmed the results of M'Nee and Renshaw as to the transmission of the disease by the injection of the blood of a trench fever patient, the periods of incubation observed also closely corresponding. The American Committee found, however, that the clear citrated plasma is also infective—that is, apparently the parasite is not intra-corpuscular. They attribute the positive results obtained with washed corpuscles to the virus being in part carried down by the centrifuge and thus being present between the corpuscles. They also found that the virus is present in the urine of trench fever patients, and sometimes in the sputum mixed with saliva; on the other hand, they were unable to detect it in the fæces. Another important result is that on rubbing up the dried urinary sediment in saline and then passing the fluid through a Chamberland L filter, they were able to set up trench fever by injection of the filtrate. The organism is thus, at least in one stage, a filter-passer. It is relatively resistant; it is not killed by drying or by exposure to sunlight for some time. It survives an exposure to 60° C. for half an hour, but is killed by a temperature of 70° C. for a like period.

BIBLIOGRAPHY.

GENERAL TEXT-BOOKS.—In English the student may for the earlier work consult the following: "Micro-organisms and Disease," E. Klein, 3rd ed., London, 1896. "Bacteriology and Infective Diseases," Edgar M. Crookshank, London, 1898. "A Manual of Bacteriology," George M. Sternberg, New York, 1st ed. 1893, 2nd ed. 1896 (this book contains a full bibliography). "Bacteria and their Products," G. S. Woodhead, London, 1891. "Bacteriological Technique," Eyre, London, 1902. Of more recent work the articles on bacteriological subjects in Clifford Albutt's "System of Medicine," London, 1906–10, are of the highest excellence, and have full bibliographies appended. Amongst other volumes are the following: "A Manual of Determinative Bacteriology," Frederick D. Chester, London, 1901. "A Text-Book of Bacteriology," P. H. Hiss and H. Zinsser, London, 1910. "Studies on Immunity," R. Muir, London, 1909. "Studies on Immunisation," A. E. Wright, London, 1909. "Practical Bacteriology, Microbiology, and Serum Therapy," Besson (translated by Hutchens), London, 1913. "A Text-Book of General Bacteriology," Jordan, 5th ed., London, 1916. "Applied Bacteriology," Browning, London, 1918.

For non-pathogenic bacteria occurring in connection with pathological work, consult Heim, *op. cit. infra*. For Fungi, see De Bary, "Comparative Morphology and Biology of the Fungi, Mycetozoa and Bacteria," transl. by Garnsey and Balfour, Oxford, 1887; Sachs, "Text-Book of Botany," ii., transl. by Garnsey and Balfour, Oxford, 1887.

In German: "Die Mikroorganismen," by Dr. C. Flügge, 3rd ed., Leipzig, 1896. "Lehrbuch der pathologischen Mykologie," by Baumgarten, Braunschweig, 1890. "Handbuch der pathogenen Mikroorganismen," Kolle and Wassermann, Fischer, Jena (second edition). "Handbuch der Technik and Methodik der Immunitätsforschung," Kraus and Levaditi, Jena, 1908 and 1909.

In French: Roger, "Les maladies infectieuses," Paris, 1902. "Les Teignes," R. Sabouraud, Paris, 1910.

PERIODICALS.—For references to current work, see (1) *Centralbl. f. Bakteriol. u. Parasitenk.*, Jena. This publication commenced in 1887. Two volumes are issued yearly. In 1895 it was divided into two parts. Abtheilung I. deals with *Medizinisch-hygienische Bakteriologie und thierische Parasitenkunde*. The volumes of this part are numbered consecutively with those of the former series, the first issued thus being vol. xvii. Commencing in 1902 with volume xxxi., each volume of Abtheilung I. was further divided into two parts, one consisting of *Originale*, the other of *Referate*. Abtheilung II. deals with *Allge-*

meine landwirtschaftlich-technologische Bakteriologie, Gärungs-physiologie und Pflanzenpathologie. The first volume is entitled Zweite Abtheilung, Bd. I. It contains original articles, *Referate*, etc. (2) *Bull. de l'Inst. Pasteur*, Paris, Masson Besides bacteriological abstracts this journal contains many valuable reviews and analyses relating to protozoology. (3) "Ergebnisse der allgemeinen Pathologie," Lubarsch and Ostertag, Wiesbaden, Bergmann. This from time to time contains valuable critical reviews.

The most complete account of the work of the year is found in the *Jahresb. ü. d. Fortschr. . . . d. path. Mikroorganismen*, conducted by Baumgarten, and published in Braunschweig. This publication commenced in 1887. Its disadvantage is that the volume for any year does not usually appear till two years later

Bacteriology is also dealt with in the *Index Medicus*. For valuable lists of papers by particular authors, see Royal Society Catalogue of Scientific Papers and Internat. Cat. Sc. Lit. (Section, Bacteriology).

The chief bacteriological periodicals are the *Journ. Path. and Bacteriol.*, Cambridge, edited by G. Sims Woodhead : the *Ztschr. f. Hyg. u. Infectionskrankh.*, Leipzig, edited by Koch and Flügge ; the *Ztschr. f. Immunitätsforschung*, Frankfort, edited by Ehrlich ; and the *Ann. de l'Inst. Pasteur*, Paris, edited by Duclaux ; *Journ. Exper. Med.*, New York, edited by Flexner ; *Journ. Hyg.*, Cambridge, edited by Nuttall ; *Journ. Med. Research*, Boston, edited by Ernst ; *Journ. Infect. Diseases*, Chicago, edited by Hektoen ; *Journ. of Royal Army Medical Corps.*

Valuable papers also from time to time appear in the *Lancet*, *Brit. Med. Journ.*, *Deutsche med. Wchnschr.*, *Berl. klin. Wchnschr.*, *Semaine méd.*, *Arch. f. Hyg.*, *Arch. f. exper. Path. u. Pharmakol.* Besides these periodicals the student may have to consult the *Reports of the Med. Off. of the Local Government Board*, which contain the reports of the medical officers, also the *Proc. Roy. Soc. London*, the *Compt. rend. Acad. d. sc.*, Paris, the *Compt. rend. Soc. de biol.*, Paris, and the *Arb. a. d. k. Gsndhtsamte.* (the first two volumes of the last were denominated *Mittheilungen*).

For general reviews on Protozoal and Tropical Diseases generally, see Manson, "Tropical Diseases," London, 1908 ; and Mense, "Handbuch der Tropenkrankheiten," Leipzig, 1906. *Journ. of Trop. Med.*, London. *Annals of Trop. Med.*, Liverpool. *Bull. de la Soc. de Path. Exotique*, Paris. *Archiv f. Schiffs u. Tropenhygiene*, Leipzig.

CHAPTER I.—General Morphology and Biology.

Consult here especially Flügge, "Die Mikroorganismen." De Bary, "Bacteria," translated by Garnsey and Bayley Balfour, Oxford, 1887. Zopf, "Zur Morphologie der Spaltpflanzen," Leipzig, 1882 ; "Beitr. z. Physiologie und Morphologie niederer Organismen," 5th ed., Leipzig, 1895. Graham-Smith, "Parasitology," iii. 17. Cohn, *Beitr. z. Biol. d. Pflanz.*, Bresl. (1876), ii. V. Nägeli, "Die niederen Pilze," Munich, 1877 ; "Untersuchungen über niedere Pilze," Munich, 1882. Migula, "System der Bakterien," Jena, 1897. Duclaux, "Traité de microbiologie," Paris, 1898–99. A. Meyer, "Die Zelle der Bakterien," Jena, 1912. For general morphological relations, see Marshall Ward, art. "Schizomycetes," *Ency. Brit.* 9th ed. xxi. 398 ; xxvi. 51. Engler and Prantl, "Die natürlichen Pflanzenfamilien," Lieferung, 129. "Schizophyta" (by W. Migula). Structure of Bacterial Cell.—Bütschli,

"Uber den Bau der Bakterien," Leipzig, 1890; "Weitere Ausführungen über den Bau der Cyanophyceen und Bakterien," Leipzig, 1896. Fischer, *op. cit.* in text. Buchner, Longard, and Riedlin, *Centralbl. f. Bakteriol. u. Parasitenk.* (1887), ii. 1. Ernst, *Ztschr. f. Hyg.* v. 428. Babés, *ibid.* v. 173. Neisser, *ibid.* iv. 165. MOTILITY.—Klein, Bütschli, Fischer, Cohn, *loc. cit.* Löffler, *Centralbl. f. Bakteriol. u. Parasitenk.* (1889), vi. 209; (1890), vii. 625. PIGMENTS.—Zopf, *loc. cit.*; Galeotti, ref. in *Centralbl. f. Bakteriol. u. Parasitenk.* (1893), xiv. 696. Babés, *Ztschr. f. Hyg.* xx. 3. SPORULATION.—Prazmowski, *Biol. Centralbl.* viii. 301. A. Koch, *Botan. Ztg.* (1888), Nos. 18–22. Buchner, *Sitzungsb. d. math.-phys. Cl. d. k. bayer. Akad. d. Wissensch. zu München*, 7th Feb. 1880. R. Koch, *Mitth. a. d. k. Gsndhtsamte.* i. 65. Dobell, *Quart. Journ. Micr. Sc.* (1909), liii. CHEMICAL STRUCTURE OF BACTERIA.—Nencki, *Ber. d. deutsch. chem. Gesellsch.* (1884), xvii. 2605. Cramer, *Arch. f. Hyg.* xvi. 154. Buchner, *Berl. klin. Wchnschr.* (1890), 673, 1084; *vide* Flügge, *op. cit.* CLASSIFICATION OF BACTERIA.—For general review, see Marshall Ward, *Ann. of Botany*, vi. 103; Migula, *loc. cit. supra.* Bosanquet, "Spirochætes," London, 1911. FOOD OF BACTERIA.—Nägeli, Cohn, *op. cit.* Pasteur, "Études sur la bière," 1876. Hueppe, *Mitth. a. d. k. Gsndhtsamte.* ii. 309. RELATIONS TO OXYGEN.—Pasteur, *Compt. rend. Acad. d. sc.* lii. 344, 1142. Kitasato and Weyl, *Ztschr. f. Hyg.* viii. 41, 404; ix. 97. RELATION TO ULTRA-VIOLET RAYS.—Browning and Russ, *Proc. Roy. Soc.*, Series B. (1917), xc. 33. TEMPERATURE.—*Vide* Flügge, *op. cit.* For thermophilic bacteria, Rabinowitsch, *Ztschr. f. Hyg.* xx. 154. Macfadyen and Blaxall, *Journ. Path. and Bacteriol.* iii. 87. ACTION OF BACTERIAL FERMENTS.—Salkowski, *Ztschr. f. Biol.*, N.F., vii. 92. Pasteur and Joubert, *Compt. rend. Acad. d. sc.* lxxxiii. 5. Sheridan Lea, *Journ. Physiol.* vi. 136. Beijerinck, *Centralbl. f. Bakteriol. u. Parasitenk.*, Abth. II. i. 221. E. Fischer, *Ber. d. deutsch. chem. Gesellsch.* xxviii. 1430. Liborius, *Ztschr. f. Hyg.* i. 115. See also Pasteur, "Royal Society Catologue of Scientific Papers." Green, "The Soluble Ferments and Fermentation," Cambridge, 1899. Oppenheimer, "Ferments," transl. by Mitchell, London, 1901. VARIABILITY.—Cohn, Nägeli, Flügge, *op. cit.* Winogradski, "Beitr. z. Morph. u. Physiol. d. Bakt.," Leipzig, 1888. Ray Lankester, *Quart. Journ. Micr. Sc.*, N.S. (1873), xiii. 408; (1876), xvi. 27, 278. NITRIFYING ORGANISMS.—Winogradski, *Ann. de l'Inst. Pasteur* (1890), iv. 213, 257, 760; (1891), v. 92, 577. Mazé, *ibid.* (1897), xi. 44; (1898), xii. 1, 263.

CHAPTER II.—METHODS OF CULTIVATION OF BACTERIA.

FOR GENERAL PRINCIPLES.—Pasteur, *Compt. rend. Acad. d. sc.* l. 303; li. 348, 675; *Ann. de chem.* lxiii. 5. Tyndall, "Floating Matter of the Air in Relation to Putrefaction and Infection," London, 1881. H. C. Bastian, "The Beginnings of Life," London, 1872. METHODS OF STERILISATION.—R. Koch, Gaffky, and Löffler, *Mitth. a. d. k. Gsndhtsamte.* i. 322. Koch and Wolffhügel, *ibid.* i. 301. CULTURE MEDIA.—See text-books, especially Kanthack and Drysdale, Eyre. Pasteur, "Études sur la bière," Paris, 1876. R. Koch, *Mitth. a. d. k. Gsndhtsamte.* i. 1. Roux et Nocard, *Ann. de l'Inst. Pasteur* (1887), i. 1. Roux, *ibid.* (1888), ii. 28. Marmorek, *ibid.* (1895), ix. 593. Kitasato and Weyl, *op. cit. supra.* P. and Mrs. Percy Frankland, "Micro-organisms in Water," London, 1894. Fuller, *Rep. Amer. Pub. Health Ass.* xx. 381.

Theobald Smith, *Centralbl. f. Bakteriol. u. Parasitenk.* (1890), vii. 502; (1893), xiv. 864. Durham, *Brit. Med. Journ.* (1898), i. 1387. "Report of American Committee on Bacteriological Methods," Concord, 1898. MacConkey, *Thompson-Yates and Johnston Lab. Rep.* vol. iii. pt. iii. 151; vol. iv. pt. i. 151; *Journ. Hyg.* v. 333. Grünbaum and Hume, *Brit. Med. Journ.* June 14, 1902. Drigalski and Conradi, *Ztschr. f. Hyg.* xxxix. 283. Endo, *Centralbl. f. Bakteriol. u. Parasitenk.* (Orig.) (1904), xxxv. 109. Conradi, *ibid.*, Beilage zu Abth. I. Bd. xlii. (1908) (Referate), p. *47. Fawcus, *Journ. R.A.M.C.* xii. 147. Sabouraud, "Les Teignes," Paris, 1910. INDOL REACTIONS.—Böhme, *Centralbl. f. Bakteriol. u. Parasitenk.* Abth. I. (Orig.) (1906), xl. 129. Steensma, *ibid.* xli. 295. Marshall, *Journ. Hyg.* vii. 581. MacConkey, *ibid.* ix. 86.

CHAPTER III.—MICROSCOPIC METHODS.

GENERAL.—Consult text-books, especially Klein, Kanthack and Drysdale, Hueppe, Günther, Heim. Kühne, "Praktische Anleitung zum mikroskopischen Nachweis der Bakterien im tierischen Gewebe," Leipzig, 1888. Also Bolles Lee, "The Microtomist's Vademecum," London, 1905 (this is the most complete treatise on the subject). Rawitz, *op. cit.* in text. Koch, *Mitth. a. d. k. Gsndhtsamte.* i. 1. Ehrlich, *Ztschr. f. klin. Med.* i. 553; ii. 710. STAINING OF BACTERIA.—Gram, *Fortschr. d. Med.* (1884), ii. No. 6. Nicolle, *Ann. de l'Inst. Pasteur* (1895), ix. 666. Van Ermengen, ref. *Centralbl. f. Bacteriol. u. Parasitenk.* (1894), xv. 969. Richard Muir, *Journ. Path. and Bacteriol.* (1898), v. 374. Mann, "Physiological Histology," Oxford, 1902. For *Romanowsky methods*, see Jenner, *Lancet* (1899), i. 370. Leishman, *Brit. Med. Journ.* (1901), i. 635; (1902), ii. 757; *Journ. R.A.M.C.* (1904), ii. 669. Giemsa, *Deutsche med. Wchnschr.* (1905), 1026; *Ann. de l'Inst. Pasteur* (1905), xix. 346. MacNeal, *Journ. Inf. Diseases* (1906), iii. 412. Wright, J. H., *Journ. Med. Research*, vii. 138. Wilson, *Journ. Exp. Med.* (1907), ix. 645. Hiss, *Journ. Exp. Med.* (1905), vi. 317. Benians, *Brit. Med. Journ.* (1916), ii. 722.

CHAPTER IV.—METHODS OF EXAMINING THE PROPERTIES OF SERUM—PREPARATION OF VACCINES—GENERAL BACTERIOLOGICAL DIAGNOSIS—INOCULATION OF ANIMALS.

GENERAL METHODS.—Wright, A. E., "Studies on Immunity," London, 1909. Muir, Robert, "Studies on Immunity," London, 1909. Ehrlich, "Gesammelte Arbeiten zur Immunitätsforschung," Berlin, 1904. These works contain methods applied in the investigation of the subjects dealt with in this chapter. The following are additional references relating to special points:—

AGGLUTINATION.—Delépine, *Brit. Med. Journ.* (1897), ii. 529, 967. Widal and Sicard, *Ann. de l'Inst. Pasteur* (1897), xi. 353. Wright, *Brit. Med. Journ.* (1897), i. 139; (1898), i. 355. Park and Collins, *Journ. Med. Research* (1904), xii. 491. Bainbridge, *Journ. Path. and Bacteriol.* (1909), xiii. 443. Winslow and Rogers, "Biological Studies by the Pupils of William Thompson Sedgwick," Boston, 1906. MacAlister, *Journ. Path. and Bacteriol.* (1913), xx. 441.

OPSONIC METHODS.—Klein, H., *Johns Hopkins Hosp. Bull.* (1907), xviii. 245. Simon, *Journ. Exp. Med.* (1907), ix. 487. Wright, "Technique of the Teat and Capillary Glass Tube," London, 1912.

WASSERMANN REACTION.—Gengou, *Ann. de l'Inst. Pasteur* (1902), xvi. 734. Moreschi, *Berl. klin. Wchnschr.* (1905), 1181; (1906), 100. Wassermann and Bruck, *Deutsche med. Wchnschr.* (1906), 100. Wassermann, Neisser, and Bruck, *ibid.* (1906), 745. M'Kenzie, *Journ. Path. and Bacteriol.* (1909), xiii. 311. Neisser, *München. med. Wchnschr.* (1909), No. 21, 1076. See also literature on syphilis.

PREPARATION OF VACCINES.—Harrison, *Journ. R.A.M.C.* (1905), iv. 313. Leishman, Harrison, Grattan, and Archibald, *ibid.* (1908), x. 583; (1908), xi. 327.

CHAPTER V.—BACTERIA OF AIR, SOIL, WATER, MILK—ANTISEPTICS.

AIR, SOIL, AND WATER.—Petri, *Ztschr. f. Hyg.* iii. 1; vi. 233. Flügge, *ibid.* xxv. 179. Sticher, *ibid.* xxx. 163. Weyl, "Handbuch der Hygiene," Jena, 1896, *et seq.* Houston, *Rep. Med. Off. Local Gov. Bd.* xxvii. (1897–98) 251; xxviii. (1898–99) 413, 439, 467; xxix. (1899–1900) 458, 489. Sidney Martin, *ibid.* xxvi. (1896–97) 231; xxvii. (1897–98) 308; xxviii. (1898–99) 382. Horrocks, "Bacteriological Examination of Water," London, 1901. Percy and G. C. Frankland, "Micro-organisms in Water," London, 1894. Dibdin, "Purification of Sewage and Water," London, 1897; *Ann. Rep. Bd. Health Mass.*, Boston, 1890, *et seq.* Savage, "The Bacteriol. Exam. of Water Supplies," London, 1906. Lewis, Rideal, and Walker, *Journ. Roy. San. Inst.* (1903), xxiv. 424. Prescott and Winslow, "Elements of Water Bacteriology," New York, 1908. Houston, "Annual Reports of Metropolitan Water Board," 1907, *et seq.*; "Reports on Research Work, Metropolitan Water Board," 1907, *et seq.* Coplans, *Journ. Path. and Bacteriol.* (1912–13), xvii. 367. MacConkey, *Journ. Hyg.* (1908), viii. 322; (1909), ix. 86. Mair, *ibid.* (1908), viii. 609. Lorrain Smith, "Third Rep. Roy. Comm. on Sewage Disposal" (1903), ii.

MILK.—Percival, "Agricultural Bacteriology," London, 1910. Marshall, "Microbiology," London, 1912. Kruse, *Centralbl. f. Bakteriol. u. Parasitenk.*, Abth. I. (Orig.) (1903), xxxiv. 737. Löhnis, *ibid.*, Abth. II. (1907), xviii. 97. MacConkey, *Journ. Hyg.* (1906), vi. 385. Bertrand and Weisweiller, *Ann. de l'Inst. Pasteur* (1906), xx. 977. Belonovsky, *ibid.* (1907), xxi. 991. Metchnikoff, *ibid.* (1908), xxii. 929; (1910), xxiv. 755. Bertrand and Duchacek, *ibid.* (1909), xxiii. 402. Dean and Todd, *Journ. Hyg.* (1902), ii. 194. Savage, "Milk and the Public Health," London, 1912.

ANTISEPTICS.—R. Koch, *Mitth. a. d. k. Gsndhtsamte.* i. 234. Behring, *Ztschr. f. Hyg.* ix. 395. Ritchie, *Trans. Path. Soc. London*, l. 256. Rideal, "Disinfection and Disinfectants," London, 1898. Chick and Martin, *Journ. Hyg.* (1908), vol. viii. 654, 698. Chick, *ibid.* vol. viii. 93. Lorrain Smith, Drennan, Rettie, and Campbell, *Brit. Med. Journ.* (1915), ii. 129. Sherman, *ibid.* Dakin, *ibid.* (1915), ii. 809. Browning, Gulbransen, Kennaway, and Thornton, *ibid.* (1917), i. 73; ii. 70.

CHAPTER VI.—RELATIONS OF BACTERIA TO DISEASE, ETC.

As the observations on which this chapter is based are scattered through the rest of the book, the references to them will be found under the different diseases.

CHAPTER VII.—Inflammatory and Suppurative Conditions.

Etiology.—Ogston, *Brit. Med. Journ.* (1881), i. 369. Rosenbach, "Mikroorganismen bei den Wundinfectionskrankheiten des Menschen,' Wiesbaden, 1884. Passet, *Fortschr. d. Med.* (1885), Nos. 2 and 3. W. Watson Cheyne, "Suppuration and Septic Diseases," Edinburgh, 1889. Grawitz, *Virchow's Archiv* (1889), cxvi. 116; *Deutsche med. Wchnschr.* (1889), No. 23. Steinhaus, "Die Aetiologie der acuten Eiterung," Leipzig, 1889. Lübbert, "Biologische Spaltpilzuntersuchung," Würzburg, 1886. Krause, *Fortschr. d. Med.* (1884), Nos. 7 and 8. Becker, *Deutsche med. Wchnschr.* (1883), No. 46.

Streptococci.—Differentiation of Varieties.—Steinhaus, *Ztschr. f. Hyg.* (1889), 518 (m. tetragenus). V. Lingelsheim, *Ztschr. f. Hyg.* x. 331; xii. 308. Behring, *Centralbl. f. Bakteriol. u. Parasitenk.* (1892), xii. 192. Knorr, *Ztschr. f. Hyg.* (1893), xiii. 427. Booker, *Johns Hopkins Hosp. Rep.*, vi. 159. Hirsch, *Centralbl. f. Bakteriol. u. Parasitenk.* (1897), xxii. 369. Libman, *ibid.* xxii. 376. Hiss, *Journ. Exper. Med.* (1905), vi. 317. Schottmüller, *München. med. Wchnschr.* (1903), 849. Gordon, *Reports Med. Off. Local Gov. Board* (1905), 388; *Lancet* (1905), ii. 1400. *Journ. Path. and Bacteriol.* (1911), xv. 323. Andrewes and Horder, *Lancet* (1906), ii. 708. Nieter, *Ztschr. f. Hyg.* (1907), lvi. 307. Ainley Walker, *Journ. Path. and Bacteriol.* (1910), xv. 124. Beattie and Yates, *ibid.* (1911), xvi. 137. Kocher and Tavel, "Vorlesungen uber chirurgische Infectionskrankheiten; die Streptomykosen," Jena, 1909. Tissier, *Ann. de. l'Inst. Pasteur* (1908), xxii. 206. Schmitz (Enterococcus), *Centralbl. f. Bakter.* (Orig.), Abth. I. (1913), lxvii. 51. Donaldson, *Journ. Path. and Bacteriol.* (1914), xviii. 469. Holman, *Journ. of Med. Research* (1916), xxxiv. 377. Blake, *ibid.* (1917), xxxvi. 99. Hæmolytic Properties.—Besredka, *Ann. de l'Inst. Pasteur* (1901), xv. 880. M'Leod, *Journ. Path. and Bacteriol.* (1912), xvi. 321. *Centralbl. f. Bacteriol. u. Parasitenk.*, Abth. I. xliii. 793, *et seq.* Sachs, *Ztschr. f. Hyg.* (1909), lxiii. 463. V. Hellens, *Centralbl. f. Bakteriol.*, Abth. I. (1913), lxviii. 642. Staphylotoxin.—Neisser and Wechsberg, *Ztschr. f. Hyg.* (1901), xxxvi. 299. Experimental Inoculation.—Christmas Dirckinck-Holmfield, "Recherches expérimentales sur la suppuration," Paris, 1888. Garré, *Fortschr. d. Med.* (1885), No. 6. Marmorek, *Ann. de l'Inst. Pasteur* (1895), ix. 593. Petruschky, *Ztschr. f. Hyg.* (1894), xvii. 59; (1894), xviii. 413. Widal and Bezançon, *Ann. de l'Inst. Pasteur* (1895), ix. 104. Thoinot et Masselin, *Rev. de med.* (1894), xiv. 449. Wright and Douglas, *Proc. Roy. Soc. Lond.* (1905), lxxiv. 147. Pathogenic Effects.—Muir, *Journ. Path. and Bacteriol.* (1901), vii. 161; *Trans. Path. Soc. Lond.* (1902), liii. 379. Welch, *Am. Med. Journ. Sc.* (1891), 439. Lemoine, *Ann. de l'Inst. Pasteur* (1895), ix. 877. Kurth, *Arb. a. d. k. Gsndhtsamte.* (1891), vii. 389. Ruediger, *Journ. Infect. Dis.* (1906), iii. 755. Antistreptococcic Serum.—Bulloch, *Lancet* (1896), i. 982, 1216. Bordet, *Ann. de l'Inst. Pasteur* (1897), xi. 177. Wright, *Clinical Journal* (1906), xxviii. 71. Levy and Hamm, *München. med. Wchnschr.* (1909), No. 34, 1728. B. Proteus.—Hauser, "Ueber Faulnissbakterien," Leipzig, 1885. Berthelot, *Ann. de l'Inst. Pasteur* (1914), xxviii. 913. Stewart, *Journ. of Hyg.* (1917), xvi. 291. Wallace and Dudgeon, *Lancet* (1915), i. 597.

Endocarditis.—Ribbert, *Fortschr. d. Med.* (1886), No. 1. Orth and Wyssokowitsch, *Centralbl. f. d. med. Wissench.* (1885), 577. Netter,

Arch. de physiol. norm. et path. (1886), viii. 106. Weichselbaum, *Wien. med. Wchnschr.* (1885), No. 41 ; (1888), Nos. 28–32 ; *Centralbl. f. Bakteriol. u. Parasitenk.* (1887), ii. 209 ; *Beitr. z. path. Anat. u. z. allg. Path.* iv. 127.

Osteomyelitis.—Lannelongue et Achard, *Ann. de l'Inst. Pasteur* (1891), v. 209.

Erysipelas.—Petruschky, *Ztschr. f. Hyg.* (1896), xxiii. 142 (with Koch, xxiii. 477). Fehleisen, "Die Aetiologie des Erysipels," Berlin, 1883.

Conjunctivitis.—Morax, *Ann. de l'Inst. Pasteur* (1896), x. 337. Eyre, *Journ. Path. and Bacteriol.* vi. 1. Müller, *Wien. med. Wchnschr.* 1897 ; Inglis Pollock, *Trans. Ophthalm. Soc.*, 1905 ; Axenfeld, in Lubarsch and Ostertag, "Ergebnisse der allgem. Pathol. u. Path. Anat.," 1901 ; "Die Bakteriologie in der Augenheilkunde," 1907 (full references). M. z. Nedden, Lubarsch and Ostertag's "Ergebnisse d. allg. Path.," (1906–9). Jahrg. xiv. Ergänzungsbd. (Full references.)

Acute Rheumatism.—Triboulet and Cayon, *Bull. Soc. méd. d. hôp. de Paris* (1898), 93. Westphal, Wassermann, and Malkoff, *Berl. klin. Wchnschr.* (1899), 638. Poynton and Paine, *Lancet* (1900), ii. 861, 932 (full references). *Trans. Path. Soc. Lond.* (1902), liii. 221 ; *Lancet*, December 1905. Beaton and Walker, *Brit. Med. Journ.* (1903), i. 237. Shaw, *Journ. Path. and Bacteriol.* (1903), ix. 158. Beattie, *ibid.* ix. 272, xiv. 432 ; *Journ. Med. Research*, xiv. 399 ; *Journ. Exper. Med.* ix. 186. Cole, *Journ. Infect. Diseases*, i. 714. Beattie, *Journ. Path. and Bacteriol.* xiv. 432. Beattie and Yates, *ibid.* xvi. 404. Steinert, *München. med. Wchnschr.* (1910), 1927. Menzer, *Ztschr. f. Hyg.* lxviii. 296.

Acne.—Unna, "Histopathology of Diseases of the Skin," 1896, p. 361. Sabouraud, *Ann. de l'Inst. Pasteur* (1897), xi. 134. Südmersen and Thompson, *Journ. Path. and Bacteriol.* (1909), xiv. 224. Fleming, *Lancet* (1909), i. 1035, 1065. Whitfield, *Proc. Roy. Soc. Med.*, Path. Sect. (1910), iii. 172. Molesworth, *Brit. Med. Journ.* (1910), ii. 1227.

CHAPTER VIII.—Inflammatory and Suppurative Conditions, *Continued*: Acute Pneumonias, Epidemic Cerebro-Spinal Meningitis.

Pneumonia.—*Historical.*—Friedländer, *Fortschr. d. Med.* (1882), i. No. 22 ; ii. 287 ; *Virchow's Archiv* (1883), lxxxvii. 319. Fraenkel, A., *Ztschr. f. klin. Med.* (1886), 401. Salvioli and Zäslein, *Centralbl. f. d. med. Wissensch.* (1883), 721. Ziehl, *ibid.* (1883), 433 ; (1884), 97. *Etiology.*—Klein, *ibid.* (1884), 529. Jürgensen, *Berl. klin. Wchnschr.* (1884), 270. Seibert, *ibid.* (1884), 272, 292. Senger, *Arch. f. exper. Path. u. Pharmakol.* (1886), 389. Diplococcus Pneumoniæ.—Kruse and Pasini, *Ztschr. f. Hyg.* ix. 279. Eyre and Washbourn, *Journ. Path. and Bacteriol.* (1897), iv. 394 ; (1898), v. 13. Neufeld and Rimpau, *Ztschr. f. Hyg.* li. 283. Cultivation of Friedländer's Pneumobacillus.—Grimbert, *Ann. de l'Inst. Pasteur* (1895), ix. 840. Pneumobacteria in Pneumonia and other Conditions.—Weichselbaum, *Wien. med. Wchnschr.* xxxvi. (1301, 1339, 1367) ; *Monatschr. f. Ohrenh.* (1888), Nos. 8 and 9 ; *Centralbl. f. Bakteriol. u. Parasitenk.* (1889), v. 33. Netter, *Bull. et mém. Soc. méd. d. hôp. de Paris* (1889) ; *Compt. rend. Acad. d. sc.* (1890) ; *Compt. rend. Soc. de biol.* lxxxvii. 34. Rosenow, *Journ. Amer. Med. Ass.* (1908), li. No. 19. Experimental Inocula-

TION.—Gamaléia, *Ann. de l'Inst. Pasteur* (1888), ii. 440. Lamar and Meltzer, *Journ. Exper. Med.* (1912), xv. 133. PATHOLOGY OF PNEUMOCOCCUS INFECTION.—Guarnieri, *Atti d. r. Accad. med. di Roma* (1888), ser. ii. iv. Fraenkel and Reiche, *Ztschr. f. klin. Med.* (1894), xxv. 230. Sanarelli, *Centralbl. f. Bakteriol. u. Parasitenk.* (1891), x. 817. Lannelongue, *Gaz. d. hôp.* (1891), 379. See also *Brit. Med. Journ.* (1901), ii. 760. Commission to Investigate Acute Resp. Dis. (Hiss and others), see *Journ. Exp. Med.* (1905), vii. pp. 403, 632. STRAINS OF PNEUMOCOCCUS.—Monographs of Rockefeller Institute, No. 7, New York, 1917. Lister, *Bull. of S. African Inst. for Med. Research*, No. 10, 1917. IMMUNISATION AGAINST PNEUMOCOCCUS.—G. and F. Klemperer, *Berl. klin. Wchnschr.* (1891), 869, 893. Foà and Bordoni-Uffreduzzi, *Deutsche med. Wchnschr.* (1886), No. 33. Emmerich, *München. med. Wchnschr.* (1891), No. 32. Issaeff, *Ann. de l'Inst. Pasteur* (1893), vii. 260. Tschistowitch and Jourewitch, *Compt. rend. Soc. de biol.* (1908), lxiv. 1044, 1095. Romer, *Archiv f. Ophthalm.* liv. 99. Neufeld and Haendel, *Arb. a. d. k. Gesundh.* (1910), 34, Heft 2 and 3. SERUM REACTIONS.—Washbourn, *Journ. Path. and Bacteriol.* (1897), iv. 394; (1898), v. 13. Neufeld and Haendel, *Ztschr. f. Immunitätsforschung* (1909), iii. 159. Rosenow, *Journ. Amer. Med. Assoc.* (1910), 1943. Lamar, *Journ. Exper. Med.* (1911), xiii. 1, 380; xiv. 256.

MENINGITIS.—*General.*—Gwyn, *Johns Hopkins Hosp. Bull.* (1899), 109. Kolle and Wassermann, *Klin. Jahrb.* (1906), 507. Bettencourt and Franca, *Ztschr. f. Hyg.* (1904), xlvi. 463. Vansteenberghe and Grysez, *Ann. de l'Inst. Pasteur* (1906), xx. 69. Elser and Huntoon, *Journ. Med. Research* (1909), xx. 377. Discussion in *Brit. Med. Journ.* (1908), ii. 1334. ETIOLOGY.—Weichselbaum, *Fortschr. d. Med.* (1887), v. 573, 620. Jaeger, *Ztschr. f. Hyg.* (1895), xix. 351. Councilman, Mallory, and Wright, "Epidemic Cerebro-spinal Meningitis," *Rep. Bd. Health, Mass.*, Boston, 1898 (full references). Albrecht and Ghon, *Wien. klin. Wchnschr.* (1901), xiv. 984; *Rev. Neur. and Psychiat.* (1907), v. 593, 686. DIPLOCOCCUS INTRACELLULARIS MENINGITIDIS.—Gordon, "Report to Local Government Board on the Micrococcus of Cerebro-spinal Meningitis," London, H.M. Stationery Office, 1907. Shennan and W. T. Ritchie, *Journ. Path. and Bacteriol.* (1908), xii. 456. MODE OF ENTRANCE AND SPREAD.—Kutscher, *Deutsche med. Wchnschr.* (1906), 1071. Goodwin and von Sholly, *Journ. Infect. Dis. Suppl.* (1906), No. 2, p. 21. Arkwright, *Journ. of Hyg.* (1907), vii. 145. Hachtel and Hayward, *Journ. Infect. Dis.* (1911), viii. 444. Shearer and Crowe, *Proc. Roy. Soc.*, Ser. B. (1917), lxxxix. 422. EXPERIMENTAL INOCULATION.—V. Lingelsheim, *Klin. Jahrb.* (1906), xv. 373. Flexner, *Journ. Exper. Med.* (1907), ix. 105. Stuart M'Donald, *Journ. Path. and Bacteriol.* (1908), xii. 442. SERUM REACTIONS.—Jaeger, *Ztschr. f. Hyg.* (1903), xliv. 225. Macgregor, *Journ. Path. and Bacteriol.* (1910), xiv. 503. Houston and Rankin, *Brit. Med. Journ.* (1907), ii. 1414. Tulloch, *Journ. Roy. Army Med. Corps* (1917), xxix. 66. ANTI-SERA.—Flexner and Jobling, *Journ. Exper. Med.* (1908), x. 141, 690. M'Kenzie and Martin, *Journ. Path. and Bacteriol.* (1908), xii. 539. Flexner, *Journ. State Med.* (1912), xx. 257. *Journ. Exper. Med.* (1913), xvii. 553. Gordon, *Brit. Med. Journ.* (1918), 110. ALLIED DIPLOCOCCI.—Dunham, *Journ. Infect. Dis., Suppl.* (1906), No. 2, p. 10. Buchanan, *Trans.* xiv.; *Internat. Cong. Hyg.* 1907. Arkwright, *Journ. of Hyg.* (1909), ix. 104. MENINGITIS DUE TO OTHER ORGANISMS.—J. Ritchie, *Journ. Path. and Bacteriol.* (1910), xiv. 615. Henry, *ibid.* (1912), xvii. 174.

During the war there have been numerous papers in *Brit. Med. Journ.*, *Lancet*, *Journ. of R.A.M.C.*, etc. *Vide*, especially, *Special Reports of Med. Research Committee* (1916–17), also *Reps. Loc. Gov. Board* (1914), New Series, No. 110.

CHAPTER IX.—GONORRHŒA, SOFT SORE.

GONORRHŒA.—*General.*—Th. Vannod, *Centralbl. f. Bakteriol. u. Parasitenk.*, Abth. I. (Orig.) (1907), xliv. 10, 110. THE GONOCOCCUS.—Neisser, *Centralbl. f. d. med. Wissensch.* (1879), 497; *Deutsche med. Wchnschr.* (1882), 279; (1894), 335. Bumm, "Der Mikroorganismus der gonorrhoischen Schleimhauterkrankunger," Wiesbaden, 1885, 2nd edition, 1887; *München. med. Wchnschr.* (1886), No. 27; (1891), Nos. 50 and 51. CULTURAL REACTIONS.—Bumm, *Centralbl. f. Gynäk.* (1891), No. 22; *Wien. med. Presse* (1891), No. 24. Bockhart, *Monatsh. f. prakt. Dermat.* (1886), v. No. 4; (1887), vi. No. 19. Steinschneider, *Berl. klin. Wchnschr.* (1890), No. 24; (1893), No. 29; Wertheim, *Wien. klin. Wchnschr.* (1890), 25; *Deutsche med. Wchnschr.* (1891), No. 50. Finger, Ghon, and Schlagenhaufer, *Arch. f. Dermat. u. Syph.* (1894), xxviii. 3, 276. Thomson, *Brit. Med. Journ.* (1917), i. 869. COMPARISON WITH ALLIED ORGANISMS.—Torrey, *Journ. Med. Research* (1908), xix. 471. Martin, *Journ. Path. and Bacteriol.* (1910), xv. 76. RELATIONS TO THE DISEASE.—*Verhandl. d. deutsche dermat. Gesellsch. I. Congress*, Wien (1889), 159. Wertheim, *Arch. f. Gynäk.* xli. Heft 1; *Centralbl. f. Gynäk.* (1891), No. 24. Lenhartz, *Berl. klin. Wchnschr.* (1898), 1138. Raskai, *Deutsche med. Wchnschr.* (1901), No. 1. Jundell, *Centralbl. f. Bakteriol. u. Parasitenk.* (1901), xxix. 224. TOXIN OF GONOCOCCUS.—De Christmas, *Ann. de l'Inst. Pasteur* (1897), xi. 609. Nicolaysen, *Centralbl. f. Bakteriol. u. Parasitenk.* (1897), xxii. 305. Rendu, *Berl. klin. Wchnschr.* (1898), 431. Wassermann, *Ztschr. f. Hyg.* xxvii. 298; *München. med. Wchnschr.* (1901), No. 8. De Christmas, *Ann. de l'Inst. Pasteur* (1900), xiv. 331. DISTRIBUTION IN TISSUES.—*Centralbl. f. Gynäk.* (1892), No. 20; *Wien. klin. Wchnschr.* (1894), 441. Heiman, *New York Med. Rec.* (1895), 769. Foulerton, *Trans. Brit. Inst. Preven. Med.* i. 40. Strong, *Journ. Am. Med. Ass.*, May 1904. Gurd, *Journ. Med. Research* (1908), xviii. 271. Brons, *Klin. Monatsbl. f. Augenheilk.* (1907), xlv. 1. RELATIONS TO JOINT AFFECTIONS. — Gerhardt, *Charité-Ann.* (1889), xiv. 241. Bordoni-Uffreduzzi, *Deutsche med. Wchnschr.* (1894), 484. König, *Berl. klin. Wchnschr.* (1900), No. 47. PATHOLOGICAL CONDITIONS.—Leyden, *Ztschr. f. klin. Med.* xxi. 607; *Deutsche med. Wchnschr.* (1893), 909. Councilman, *Am. Journ. Med. Sc.* (1893), cvi. 277. Lang, *Arch. f. Dermat. u. Syph.* (1892), xxiv. 1007; *Wien. med. Wchnschr.* (1891), No. 7; "Der Venerische Katarrh, dessen Pathologie und Therapie," Wiesbaden, 1893. Klein, *Monatschr. f. Geburtsh. u. Gynaek.* (1895), i. 33. Michaelis, *Ztschr. f. klin. Med.* (1896), xxix. 556. Thayer and Lazear, *Journ. Exper. Med.* (1899), iv. 81. Colombini, *Centralbl. f. Bakteriol. u. Parasitenk.* (1898), xxiv. 955. Bressel, *München. med. Wchnschr.* (1903), No. 13. Möller, *Arch. f. Dermat. u. Syph.* (1904), lxxi. 269. Prochaska, *Arch. f. klin. Med.* (1906), lxxxiii. Heft 1–2. Hamilton, *Journ. Infect. Dis.* (1908), v. 133. METHODS OF DIAGNOSIS. —Heiman, *New York Med. Rec.* (1896), Dec. 19.

SOFT SORE.—Ducrey, *Monatsh. f. prakt. Dermat.* (1889), ix. 221. Krefting, *Arch. f. Dermat. u. Syph.* (1892), 263. Jullien, *Journ. d.*

mal. cutan. et syph. (1892), 330. Unna, *Monatsh. f. prakt. Dermat.* (1892), 475; (1895), 61. Quinquand, *Semaine méd.* (1892), 278. Petersen, *Centralbl. f. Bakteriol. u. Parasitenk.* xiii. 743; *Arch. f. Dermat. u. Syph.* (1894), 419. Audrey, *Monatsh. f. prakt. Dermat.* (1895), 267. Colombini, *Centralbl. f. Bakteriol. u. Parasitenk.* xxv. 254. Nicolle, *Presse médicale* (1900), 304. Bezançon, Griffon, and Le Sourd, *Ann. de dermat. et de syphilolog.* (1901), tome ii. 1. Lenglet, *ibid.* (1901), tome ii. 209. Simon, *Compt. rend. Soc. biol.* (1902), 547. Tomasczewski, *Ztschr. f. Hyg.* (1903), Bd. 43, p. 327. Davis, *Journ. of Med. Research* (1903), ix. 401. Watabiki, *Journ. Infect. Dis.* (1910), vii. 159. Hamilton, *Journ. Am. Med. Assoc.* (1910), liv. No. 15. Halberstaedter, *Berl. klin. Wchnschr.* (1910), 1496.

CHAPTER X.—Tuberculosis.

General.—Baumgarten, "Lehrb. d. path. Myk.," 1890. Straus, "La Tuberculose et son bacille," Paris, 1895. Salmon and Smith, "Tuberculosis," *U.S. Department of Agriculture*, Washington, 1904. Wolbach and Ernst, *Journ. Med. Research*, x. 313. "Reports of the Royal Commission on Tuberculosis," London, 1904, 1911.

Historical.—Klencke, "Untersuchungen und Erfahrungen im Gebiet der Anatomie," etc., Leipzig, 1843. Villemin, "De la virulence et de la spécificité de la tuberculose," Paris, 1868. Cohnheim and Fraenkel, "Experimentelle Untersuchungen uber der Ubertragbarkeit der Tuberculose auf Thiere." Cohnheim, "Die Tuberculose vom Standpunkt der Infections-lehre," 1879. Various authors, "Discussion sur la tuberculose," *Bull. Acad. de med.* (1867), xxxii., xxxiii. Armanni, "Novimento med.-chir.," Naples, 1872.

Tubercle Bacillus.—Koch, *Berl. klin. Wchnschr.* (1882), 221; *Mitth. a. d. k. Gsndhtsamte.*, 1884. Bulloch, *Lancet* (1901), ii. 243. Williams, *ibid.* (1883), i. 312. Pawlowsky, *Ann. de l'Inst. Pasteur*, (1892), vi. 116. Staining Reactions.—Much, *Beitr. zu Klin. d. Tuberk.* (1907), viii. 85, 357. Wirths, *München. med. Wchnschr.* (1908), lv. 1687. Trauholz, *New York Med. Rec.* (1908), 60. Herman, *Ann. de l'Inst. Pasteur* (1908), xxii. 92. Miller, *Journ. Path. and Bacteriol.* (1916), xxi. 41. Cultural Reactions.—Nocard and Roux, *Ann. de l'Inst. Pasteur* (1887), i. 19. Pawlowsky, *ibid.* (1888), ii. 303. Sander, *Arch. f. Hyg.* (1892), xvi. 238. Coppen Jones, *Centralbl. f. Bakteriol. u. Parasitenk.* (1892), xvii. 1. Hofmann, *Wien. med. Wchnschr.* (1894), No. 38, 712. Frugoni, *Centralbl. f. Bakteriol. u. Parasitenk.* (Orig.) (1910), liii. 553. Twort, *Proc. Roy. Soc. Lond.*, B. lxxxi., March 1909. Cruickshank, *Brit. Med. Journ.* (1912), ii. 1298. Cornet, *Ztschr. f. Hyg.* v. 191. Experimental Inoculation.—Héricourt and Richet, *Bull. méd.* (1892), 741, 966. Bollinger, *Verhandl. d. Gesellsch. deutsche Naturf. u. Aertze* (1890), ii. 187.

Varieties of Tuberculosis.—Human and Bovine. — Nocard, "The Animal Tuberculoses" (transl.), London, 1895. T. Smith, *Journ. Exper. Med.* (1898), iii. 451. Koch, *Brit. Med. Journ.* (1901), ii. 189; *Trans. Internat. Congr. of Tuberc.*, London, 1901. Delépine, *Brit. Med. Journ.* (1901), ii. 1224. Ravenel, *Univ. Pennsylvania Med. Bulletin*, May 1902. Koch, *Deutsche med. Wchnschr.* (1902), No. 48. De Jong, *Centralbl. f. Bakteriol. u. Parasitenk.* (1905), xxxviii. (Orig.), 146. Ravenel, *Univ. of Pennsylvania Med. Bulletin*, 1902. Kossel, Weber, and Heuss, *Tuberk. Arbeit. a. d. kaiserl. Gsndhtsmte.*, Berlin,

1904–1905 and onwards. Park, *Collected Studies*, Dept. of Health (1908–10), iv., v. Fraser, *Journ. Exper. Med.* (1912), xvi. 432. Wang, *Journ. Path. and Bacteriol.* (1916), xxi. 14, 131. Griffith, *ibid.* (1916), xxi. 54; Mitchell, *ibid.* (1916), xxi. 248. AVIAN TUBERCULOSIS.—Straus and Gamaléia, *Arch. de méd. exper. et d'anat. path.* (1892), iii. No. 4. Courmont, *Semaine méd.* (1893), 53; *Revue de méd.* (1891), No. 10. Maffucci, "Sull' azione tossica dei prodotti del bacillo della tuberculose"; *Centralbl. f. allg. Path. u. path. Anat.* (1890), i. 409. Kruse, *Beitr. z. path. Anat. u. z. allg. Path.* xii. 221. Straus and Würtz, *Cong. p. l'étude de la tuberculose*, Paris, July 1888. Nocard, *Ann. de l'Inst. Pasteur* (1898), xii. 561. de Jong, *Ann. de l'Inst. Pasteur* (1910), xxiv. 895. FISH TUBERCULOSIS.—Bataillon, Dubard and Terre, *Compt. rend. Soc. de biol.* (1897), 446. Dubard, *Rev. de la tubercul.* (1898), 13, 129. Weber and Tante, *Tuberculosearbeiten a. d. kaiserl. Gsndheitsamte.*, Berlin (1905), 110.

OTHER ACID-FAST BACILLI. — Moeller, *Deutsche med. Wchnschr.* (1898), 376. *Centralbl. f. Bakteriol. u. Parasitenk.* xxv. 369; *ibid.* xxx. 513. Petri, *Arb. a. d. k. Gsndhtsamte.* (1898), 1. Rabinowitch, *Deutsche med. Wchnschr.* (1897), No. 26; (1900), No. 16; *Ztschr. f. Hyg.* xxvi. 90. Korn, *Arch. f. Hyg.* xxxvi. 57; *Centralbl. f. Bakteriol. u. Parasitenk.* xxvii. 481. Schulze, *Ztschr. f. Hyg.* xxxi. 153. M. Tobler, *ibid.* xxxvi. 120. Lubarsch, *ibid.* xxxi. 187. Hölscher, *Centralbl. f. Bakteriol. u. Parasitenk.* xxix. 425. Potet, "Étude sur les bacilles dites 'acidophiles,'" Paris, 1902. Abbot and Gildersleeve, *Univ. of Pennsylvania Med. Bulletin*, June 1902. Johne and Frothingham, *Deutsche Ztschr. f. Thiermed.* (1895), 438. M'Fadyean, *Journ. Compar. Path.* xx. (1907), 48. Philibert, "Les pseudo-bacilles acido-résistants," Paris, 1908. Twort and Ingram, *Proc. Roy. Soc.*, B. lxxxiv. (1912), 517.

ACTION OF DEAD TUBERCLE BACILLI.—Prudden and Hodenpyl, *New York Med. Rec.* (1891), 636. Vissman, *Virchow's Archiv* (1892), cxxix. 163. Stockman, *Brit. Med. Journ.* (1898), ii. 601. SPECIFIC REACTIONS.—Koch, *Deutsche med. Wchnschr.* (1890), No. 46A; (1891) Nos. 3 and 43; (1897), No. 14. Weyl, *Deutsche med. Wchnschr.* (1891), 256. Buchner, *Centralbl. f. Bakteriol. u. Parasitenk.* (1892), xi. 488. PHENOMENA OF SUPERSENSITIVENESS.—Kühne, *Ztschr. f. Biol.* (1892), xxix. 1; (1894), xxx. 221. Krehl, *Arch. f. exper. Path. u. Pharmakol.* xxxv. 222. Krehl and Matthes, *ibid.* xxxvi. 437. v. Pirquet, *Berl. klin. Wchnschr.* (1907). *Vide* also article on "Kutane u. konjunktivale Tuberkulin reaktion," in Kraus and Levaditi's *Technik u. Methodik der Immunitätsforschung*, Bd. 1. 1035. Wolff-Eisner, *Berl. klin. Wchnschr.*, 1907. Calmette, *Comp. rend. Acad. d. Sc.* (1907), 1324. Pasteur* (1899), xiii. 568, 801. Rist, *Compt. rend. Soc. de biol.* (1903), No. 25. Morgenroth, *Ztschr. f. Hyg.* xlviii. 177. Theobald Smith, *Journ. Med. Research* (1905), xiii. 341. Nicolle and Loiseau, *Ann. de l'Inst. Pasteur* (1911), xxv. 150. PREPARATION OF TOXINS.—Spronck, *Centralbl. f. allg. Path. u. path. Anat.* i. No. 25; iii. No. 1. ANTI-DIPHTHERITIC SERUM.—Roux and Martin, *Ann. de l'Inst. Pasteur* (1894), viii. 609. Cartwright, Wood, *Lancet* (1896), i. 980, 1076; ii. 1145. Behring, "Abhandlungen z. ätiol. Therap. v. anst. Krankh.," Leipzig, 1893; "Bekämpfung der Infectionskrankheiten," Leipzig, 1894. Ehrlich and Wassermann, *Ztschr. f. Hyg.* xviii. 239. Ehrlich and Kossel, *ibid.* xvii. 486. Ehrlich, Kossel, and Wassermann, *Deutsche med. Wchnschr.* (1894), 353. Madsen, *Ztschr. f. Hyg.* xxiv. 425. Salomonsen and Madsen, *Ann. de l'Inst. Pasteur* (1898), xii. 763. Neisser, *Berl. klin. Wchnschr.* (1904), No. 11. IMMUNISATION AGAINST DIPHTHERIA.—Klein, *Brit. Med. Journ.* (1894), ii. 1393; (1895), i. 100; *Rep. Med. Off. Local Govt. Board* (1890–91), 219; (1891–92), 125. Behring, "Die Geschichte der Diphtherie," Leipzig, 1893. VIRULENCE OF B. DIPHTHERIÆ.—Graham-Smith, *Journ. Hyg.* (1904), iv. 258. Arkwright, *ibid.* (1911), xi. 409.

PSEUDO-DIPHTHERIA BACILLI (DIPHTHEROID BACILLI).—Ford Robertson, *Brit. Med. Journ.* (1903), ii. 1065, and *Rev. of Neurol. and Psych.*, vols. i.–iii. HOFMANN'S BACILLUS.—v. Hofmann, *Wien. med. Wchnschr.* (1888), Nos. 3 and 4. Cobbett and Phillips, *Journ. Path. and Bacteriol.* (1897), iv. 193. Peters, *ibid.* 181. Escherich, *Berl. klin. Wchnschr.* (1893), Nos. 21, 22, 23. Prochaska, *Ztschr. f. Hyg.* xxiv. 373. Cobbett, *Journ. of Hyg.* (1901), i. 485. Petrie, *ibid.* (1905), v. 134. Boycott, *ibid.* v. 223. DIFFERENTIATION OF DIPHTHERIA BACILLI.—Neisser, *Ztschr. f. Hyg.* xxiv. 443; *Hyg. Rundsch.* (1903), xiii. 705. Graham-Smith, *Journ. Hyg.* (1906), vi. 286. Knapp, *Journ. Med. Research* (1904), vii. 475. Priestley, *Proc. Roy. Soc. Med.* (1911), v. pt. iii. 46. Gordon, *Rep. Med. Off. of Health, Local Govt. Board* (1901–1902), 418. Hine, *Journ. Path. and Bacteriol.* (1913), xviii. 75. Zingher and Soletsky, *Journ. Infect.*

Diseases (1915), xvii. 454. Kolmer and Moshage, *ibid.* (1916), xix. 1. Cary, *ibid.* (1917), xx. 244.

CHAPTER XVII.—TETANUS, ETC.

TETANUS.—HISTORICAL.—Nicolaier, "Beiträge zur Aetiologie des Wundstarrkrampfes," Inaug. Diss., Göttingen, 1885. Rosenbach, *Arch. f. klin. Chir.* xxiv. 306. Carle and Ratone, *Gior. d. r. Accad. di med. di Torino*, 1884. Kitasato, *Ztschr. f. Hyg.* vii. 225. B. TETANI.—Kitasato and Weyl, *ibid.* viii. 41, 404. Kitt, *Jahresb. d. k. Centr.-Thierarznei-Schule in München*, 1883–84. Chauveau and Arloing, *Arch. vet.* (1884), 366, 817. TOXINS OF TETANUS BACILLUS.—Kitasato, *Ztschr. f. Hyg.* x. 267. Vaillard and Rouget, *Ann. de l'Inst. Pasteur* (1892), vi. 385. Noble, *Journ. Inf. Dis.* (1915), xvi. 132. Brieger and Fraenkel, *Berl. klin. Wchnschr.* (1890), 241, 268. Sidney Martin, *Rep. Med. Off. Local Govt. Board* (1893–94), 497; (1894–95), 505. Uschinsky, *Centralbl. f. Bakteriol. u. Parasitenk.* xiv. 316. Madsen, *Ztschr. f. Hyg.* (1900), xxxii. 214. Ritchie, *Journ. of Hyg.* (1901), i. 125. Danysz, *Ann. de l'Inst. Pasteur* (1899), xiii. 156. Marie and Morax, *ibid.* (1902), xvi. 818. Meyer and Ransom, *Proc. Roy. Soc. London*, lxxii. 26; *Arch. f. exper. Path. u. Pharmakol.*, Leipzig (1903), xlix. 269. Roux and Borrel, *Ann. de l'Inst. Pasteur* (1898), xii. 225. IMMUNITY AGAINST TETANUS.—Vaillard, *Ann. de l'Inst. Pasteur* (1892), vi. 224, 676. Behring, *Zeitschr. f. Hyg.* (1892), xii. 1, 45. Tizzoni and Cattani, *Centralbl. f. Bakteriol. u. Parasitenk.* ix. 189, 685. Henderson Smith, *Journ. Hyg.* (1907), vii. 205. Eisler and Pibram, in Kraus and Levaditi's *Handbuch* (1908), i. 103. ANTITETANIC SERUM.—Kitasato, *Ztschr. f. Hyg.* xii. 256. Behring, "Abhandlungen z. ätiol. Therap. v. anst. Krankh.," Leipzig, 1893; "Blutserumtherapie," Leipzig, 1892; "Das Tetanus-heilserum," Leipzig, 1892. Tizzoni and Cattani, *Arch. f. exper. Path. u. Pharmakol.* xxvii. 432. Bruce, *Lancet* (1916), ii. 929; (1917), i. 680; *Brit. Med. Journ.* (1917), i. 118; War Office Memorandum, *Lancet* (1916), i. 873. Leishman and Smallman, *ibid.* (1917), i. 131.

MALIGNANT ŒDEMA.—BACILLUS OF MALIGNANT ŒDEMA.—Pasteur, *Bull. Acad. de med.*, 1881, 1887. Koch, *Mitth. a. d. k. Gsndhtsamte.* i. 54. Kerry and Fraenkel, *Ztschr. f. Hyg.* (1898), xii. 204. Leclainche and Vallée, *Ann. de l'Inst. Pasteur* (1900), xiv. 590. CULTURAL REACTIONS.—W. R. Hesse, *Deutsche med. Wchnschr.* (1885), xi. 214. Liborius, *Ztschr. f. Hyg.* i. 115. EXPERIMENTAL INOCULATION.—Charrin and Roger, *Compt. rend. Soc. de biol.* (1887), ser. viii. vol. iv. p. 408. IMMUNITY.—Roux and Chamberland, *Ann. de l'Inst. Pasteur*, i. 562. Sanfelice, *Ztschr. f. Hyg.* xiv. 339.

BACILLUS BOTULINUS.—V. Ermengem, *Centralbl. f. Bakteriol. u. Parasitenk.* (1896), xix. 443; *Ztschr. f. Hyg.* (1901), xxvi. 1. Kempner, *ibid.* xxvi. 481. Kempner and Schepilewsky, *ibid.* (1901), xxvii. 213. Kempner and Pollack, *Deutsche med. Wchnschr.* (1897), No. 32. Brieger and Kempner, *ibid.* (1897), No. 33. Marinesco, *Compt. rend. Soc. de. biol.* (1896), No. 31. Schneidemühl, *Centralbl. f. Bakteriol. u. Parasitenk.* (1898), xxiv. 577, 619. Römer, *ibid.* (1900), xxvii. 857. Madsen, in Kraus and Levaditi's *Handbuch* (1908), i. 137; ii. 134. Leuchs, *Ztschr. f. Hyg. u. Infektionskrankh.* (1910), lxv. 55.

QUARTER-EVIL.—See Nocard and Leclainche, "Les maladies microbiennes des animaux," Paris, 1896. Arloing Cornevin, et Thomas,

"Le charbon symptomatique du bœuf," Paris, 1887. Nocard and Roux, *Ann. de l'Inst. Pasteur* (1888), i. 256. Roux, *ibid.* ii. 49. See also *Journ. Comp. Path. and Therap.* iii. 253, 346; viii. 166, 233. Grassberger and Schattenfroh, in Kraus and Levaditi's *Handbuch* (1908), i. 161; ii. 186. Eisenberg, *Comp. rend. Soc. de biol.* No. 62, 491, 537, 613. Kitt, see Ref. in *Centralbl. f. Bakteriol.* (Ref.) (1903), xxxii. 359. Leclainche and Vallée, *Ann. de l'Inst. Pasteur* (1900), xiv. 202.

Bacillus Ærogenes Capsulatus.—Welch and Nuttall, *Bull. Johns Hopkins Hosp.* (1892), 81. Welch and Flexner, *Journ. Exper. Med.* i. 5. E. Fraenkel, *Centralbl. f. Bakteriol. u. Parasitenk.* (1893), xiii. 13. Dunham, *Bull. Johns Hopkins Hosp.* (1897), 68. Norris, *Am. Journ. Med. Sc.* cxvii. 172. Veillon and Zuber, *Arch. de med. expér. et d'anat. path.* (1898), x. 517. Howard, *Johns Hopkins Hosp. Reps.* (1900), ix. 461. Simonds, *Monograph, Rockefeller Inst.* (1915), No. 5. Wright, *Proc. Roy. Soc. Med.* pt. i. (1917), x. 1. Bull and Pritchett, *Journ. Exper. Med.* (1917), xxvi. 119. M'Nee and Shaw Dunn, *Brit. Med. Journ.*, 1917†.

Various Anaerobes.—V. Hibler. "Untersuchungen u. d. path. Anaeroben," Jena, 1908. Bienstock, *Annal. de l'Inst. Pasteur* (1906), xx. 497. Metchnikoff, *ibid.* (1908), xxii. 929. Fleming, *Lancet* (1905), ii. 376. Weinberg, *Glasgow Med. Journ.* (1916), i. 241. Weinberg and Seguin, *Compt. rend. Soc. de biol.* (1915), lxxviii. 507, 686; (1916), lxxix. 116; *Annal. de l'Inst. Pasteur* (1917), xxxi. 442. Robertson, M., *Journ. of Path. and Bacteriol.* (1916), xx. 327. Henry, *ibid.* (1917), xxi. 344. Wolf and Harris, *ibid.* (1917), xxi. 386. Dean and Mouat, *Journ. R.A.M.C.* (1916), xxvi. 189, 834. M'Intosh, *Med. Research Com.*, *Spec. Rep. Ser.* No. 12, 1917; *Reps. Anaerob. Com.*, Ap. 12, 1918.

Fusiform Bacilli.—Babés, in Kolle and Wassermann's *Handbuch*, Ergänz-Bd. i. 271. Vincent, *Ann. de l'Inst. Pasteur* (1896), x. 492; (1899), xiii. 609. Veillon and Zuber, *Arch. de méd. expér.* (1898), x. 517. Bernheim, *Centralbl. f. Bakteriol. u. Parasitenk.* (1898), xxiii. 171. Plaut, *Deutsche med. Wchnschr.* (1904), 920. Beitzke, *Centralbl. f. Bakteriol. u. Parasitenk.* (Ref.) (1904), xxxv. 1. Ellermann, *ibid.* (Orig.) (1904), xxxvii. 729; (1905), xxxviii. 383; *Ztschr. f. Hyg.* (1907), lvi. 453. Veszpremi, *Centralbl. f. Bakteriol. u. Parasitenk.* (Orig.) (1905), xxxviii. 136. Weaver and Tunnicliff, *Journ. Infect. Diseases* (1905), ii. 446; (1906), iii. 190. Blumer and MacFarlane, *Am. Journ. Med. Sc.* cxxi. 527. Tunnicliff, *Journ. Infect. Diseases* (1911), viii. 455. Peters, *ibid.* (1911), viii. 455. Blühdorn, *Deutsche med. Wchnschr.* (1911), 1154. Costa, *Compt. rend. Soc. de biol.* (1912), lxxii. 847.

CHAPTER XVIII.—Cholera.

Etiology.—Koch, *Rep. of First Cholera Conference*, 1884 (*v.* "Microparasites in Disease," *New Sydenham Soc.*, 1886). Pettenkofer, *München. med. Wchnschr.* (1892), xxxix. No. 46; (1894), No. 10. Sawtschenko, *Centralbl. f. Bakteriol. u. Parasitenk.* (1892), xii. 893. Sanarelli, *Ann. de l'Inst. Pasteur* (1893), vii. 693. Rumpf, "Die Cholera Asiatica and Nostras," Jena, 1898. Cholera Spirillum.—Klein, *Rep. Med. Off. Local Govt. Board*, 1893; "Micro-organisms and Disease," London, 1896. Cultural Reactions.—Dieudonné, *Centralbl. f. Bakteriol. u. Parasitenk.* (Orig.) (1909), i. 107. Greig, *Ind. Journ. Med. Research* (1914), ii. 623. Powers of Resistance.—Pfuhl, *Ztschr. f. Hyg.* xii.

509. Zlatogoroff, *Centralbl. f. Bakteriol. u. Parasitenk.* (Orig.) (1911), lviii. 14. EPIDEMIOLOGY.—*Centralbl. f. Bakteriol. u. Parasitenk.* (Ref.) (1909), xliv. 1 *et seq.*; Stevens, *Brit. Med. Journ.* (1911), i. 681. EXPERIMENTAL INOCULATION.—Nikati and Rietsch, *Compt. rend. Acad. d. sc.* xcix. 928, 1145. Kolle, *Ztschr. f. Hyg.* (1894), xvi. 329. Isaeff and Kolle, *ibid.* xviii. 17. Grüber and Wiener, *Arch. f. Hyg.* xiv. 241. PATHOGENIC PROPERTIES.—Reincke, *Deutsche med. Wchnschr.* (1894), 795. Rumpel, *ibid.* (1893), 160. Kulescha, *Klin. Jahrb.* (1910), xxiv. 137. Greig, *Ind. Journ. Med. Research* (1915), iii. 259, 397. TOXINS.—Bosc, *Ann. de l'Inst. Pasteur* (1895), ix. 507. Pfeiffer, *Ztschr. f. Hyg.* xi. 373. Sobernheim, *ibid.* xiv. 485. Wesbrook, *Ann. de l'Inst. Pasteur*, viii. 318. Scholl, *Berl. klin. Wchnschr.* (1890), No. 41. Hueppe, *Deutsche med. Wchnschr.* (1889), No. 33. Pfeiffer in Flügge, "Die Microorganismen," 3rd ed. 1896. See also *Supplement to Centralbl. f. Bakteriol.* (Ref.) (1909), xlii. 1. Huntemüller, *Ztschr. f. Hyg.* (1911), lxvii. 221. IMMUNITY.—Wassermann, *Ztschr. f. Hyg.* (1893), xiv. 35. Fraenkel and Sobernheim, *Hyg. Rundschau* (1884), iv. 97. Pfeiffer and Wassermann, *Ztschr. f. Hyg.* (1893), xiv. 46. Klemperer, *Deutsche med. Wchnschr.* (1894), 435; *Berl. klin. Wchnschr.* (1892), 969. Issaeff, *Ztschr. f. Hyg.* (1894), xvi. 287. Pfeiffer, in Flügge's "Die Microorganismen," 3rd ed. 1896. SERUM OF CHOLERA CONVALESCENTS.—Lazarus, *Berl. klin. Wchnschr.* (1892), 1071. Achard and Bensaude, *Semaine méd.* (1897), 151. Greig, *Ind. Journ. Med. Research* (1915), ii. 733. ANTICHOLERA INOCULATION.—Haffkine, *Brit. Med. Journ.* (1895), ii. 1541; *Indian Med. Gaz.* (1895), vol. xxx. No. 1; "Anticholera Inoculation," *Rep. San. Com. India*, Calcutta, 1895. A. Macfadyen, *Centralbl. f. Bakteriol.* (Orig.), xlii. 365. METHODS OF DIAGNOSIS.—Koch, *Ztschr. f. Hyg.* (1893), xiv. 319. Voges, *Centralbl. f. Bakteriol.* (1894), xv. 453. Dieudonné, *ibid.* (1893), xiv. 323. Kraus and Pibram, *ibid.* (Orig.) (1906), xli. 15, 155. Kraus and Prantschoff, *ibid.* 377, 480. Gotschlich, *Scient. Reps. Sanit. Marit. and Quarit. Council of Egypt*, Alexandria, 1905, 1906. For discussion, vide *Supplements to Centralbl. f. Bakteriol.* (Ref.) (1906), xxxviii. 84; (1909), xlii. 1. Dunbar, *Berl. klin. Wchnschr.* (1902), No. 39. Ottolenghi, *ibid.* (Orig.) (1911), lviii. 369. Schürmann u. Abelin, "Der Augenblickliche Stand der bakteriologischen Choleradiagnose," Jena, 1912.

SPIRELLA RESEMBLING CHOLERA ORGANISM.—Dunbar, *Arb. a. d. k. Gesundheits.* (1894), ix. 379. Cunningham, *Scient. Mem. Med. Off. India*, 1890 and 1894. Pestana and Bettencourt, *Centralbl. f. Bakteriol. u. Parasitenk.* (1894), xvi. 401. Celli and Santori, *ibid.* xv. 789. Ivanoff, *Ztschr. f. Hyg.* (1893), xv. 485. Greig, various papers in *Ind. Journ. Med. Research* (1913), i. *et seq.* METCHNIKOFF'S SPIRILLUM.—Metchnikoff, *Ann. de l'Inst. Pasteur*, vii. 403, 562; viii. 257, 529. Gamaléia, *ibid.* ii. 482.

CHAPTER XIX.—INFLUENZA, ETC.

INFLUENZA.—B. INFLUENZÆ.—Pfeiffer, Kitasato, and Canon, *Deutsche med. Wchnschr.* (1892), xviii. 28, and *Brit. Med. Journ.* (1892), i. 128. Babés, *Deutsche med. Wchnschr.* xviii. 113. Pfeiffer and Beck, *ibid.* 465. Pfuhl, *Centralbl. f. Bakteriol. u. Parasitenk.* (1892), xi. 397. PATHOGENIC PROPERTIES.—Klein, *Rep. Med. Off. Local Govt. Board* (1889–92), 85. Pfeiffer, *Ztschr. f. Hyg.* xiii. 357. Huber, *ibid.* (1893), xv. 454. Peilicke, *Berl. klin. Wchnschr.* (1894), xxxi. 534. Neisser, *Deutsche med.*

Wchnschr. (1903), No. 26. Thursfield, *Quart. Journ. Med.* (1910), iv. 7. Wassermann, *Deutsche med. Wchnschr.* (1900), No. 28. Clemens, *München. med. Wchnschr.* (1900), No. 27. DISTRIBUTION IN THE BODY.—Pfuhl and Walter, *Deutsche med. Wchnschr.* (1896), 82, 105. Pfuhl, *Ztschr. f. Hyg.* (1897), xxvi. 112. Wynecoop, *Journ. Med. Ass.*, February 1903. Auerbach, *Ztschr. f. Hyg.* (1904), xlvii. 259. Ghedini, *Centralbl. f. Bakteriol. u. Parasitenk.* (Orig.) (1907), xliii. 407. EXPERIMENTAL INOCULATION.—Cantani, *Ztschr. f. Hyg.* (1896), xxiii. 265. Wollstein, *Journ. Exper. Med.* (1910), xiv. 73 ; *ibid.* (1915), xxii. 445. DIAGNOSIS OF INFLUENZA.—Kruse, *Deutsche med. Wchnschr.* (1894), 513. PSEUDO-INFLUENZA BACILLI.—Jochmann, in Lubarsch and Ostertag's *Ergeb. d. allgc. Pathol.* (1909), xiii. Abth. I. 107. Davis, *Journ. Infect. Diseases* (1912), x. 259.

WHOOPING-COUGH. — ETIOLOGY. — Jochmann, *Arch. f. klin. Med.* lxxxiv. 470. Jochmann and Krause, *Ztschr. f. Hyg.* (1901), xxxvi. 193. Spengler, *Deutsche med. Wchnschr.* (1897), 830. Davis, *Journ. Infect. Dis.* (1906), iii. 1. Bordet and Gengou, *Centralbl. f. Bakteriol. u. Parasitenk.* (1909) (Ref.), xliii. 273. Bordet, *Bull. de l'Acad. Roy. de Med. de Belgique* (1908), 4th ser. xxii. 729. Arnheim, *Berl. klin. Wchnschr.* (1908), 1453. CHARACTERS OF THE BACILLUS.—Bordet and Gengou, *Ann. de l'Inst. Pasteur* (1906), xx. 731 ; (1907), xxi. 720. Klimenko, *Centralbl. f. Bakteriol. u. Parasitenk.* (Orig.), xlviii. 64 ; l. 305 ; lvi. 497. Delcourt, *ibid.* (Ref.), Abth. I. (1911), xlix. 637. PATHOGENIC PROPERTIES.—Bordet and Gengou, *Ann. de l'Inst. Pasteur* (1907), xxiii. 415. Fraenkel, *München. med. Wchnschr.* (1908), 1683. Wollstein, *Journ. Exper. Med.* (1909), xi. 41. METHODS OF EXAMINATION.—Gengou and Brunard, *Bull. de l'Acad. Roy. de Med. de Belgique* (1910), xxiv. 329.

PLAGUE.—GENERAL.—"Reports on Plague Investigations in India," *Journ. Hyg.* (1906), vi. 422 ; (1909), vii. 323 ; (1908), viii. 162 ; (1910), x. 315. BACILLUS OF PLAGUE.—Kitasato, *Lancet* (1894), ii. 428. Yersin, *Ann. de l'Inst. Pasteur* (1894), viii. 662. Yersin, Calmette, and Borrel, *Ann. de l'Inst. Pasteur* (1895), ix. 589. Gordon, *Lancet* (1899), i. 688. Netter, "La peste et son bacille," Paris, 1900. Mitth. d. deutschen Pest-Kommission, *Deutsche med. Wchnschr.* (1897), Nos. 17, 19, 31, 32. "Report of the India Plague Commission (1898–99)," London, 1900–1901. Also numerous papers in the *Lancet* and *Brit. Med. Journ.*, 1897–1901. PATHOGENIC PROPERTIES.—Aoyama, *Centralbl. f. Bakteriol. u. Parasitenk.* (1896), xix. 481. Childe, *Brit. Med. Journ.* (1898), ii. 858. EXPERIMENTAL INOCULATION.—Lowson, *Lancet* (1895), ii. 199. Wyssodowitz and Zabolotny, *Ann. de l'Inst. Pasteur* (1897), xi. 663. MODE OF INFECTION.—Simond, *Ann. de l'Inst. Pasteur* (1898), xii. 625. Ogata, *Centralbl. f. Bakteriol. u. Parasitenk.* (1897), xxi. 769. Gautier, Const, and Rayband, *Compt. rend. Soc. biol.* (1910), lxviii. 941. C. J. Martin, *Brit. Med. Journ.* (1911), ii. 1249. EPIDEMIOLOGY.—Regarding Glasgow epidemic, see *Brit. Med. Journ.* (1900), ii. Lamb, "The Etiology and Epidemiology of Plague," Calcutta, 1908. Kitasato, *Trans. Internat. Cong. Med.* (1913), sect. xxi. 1. Liston, *ibid.* 9. TOXINS.—Markl, *Centralbl. f. Bakteriol. u. Parasitenk.* (1898), xxiv. 641, 728 ; (1901), xxix. 810. PREVENTIVE INOCULATION.—Haffkine, *Brit. Med. Journ.* (1897), i. 424. Liston, *Report Bombay Bact. Lab.* (1908), ii. ANTI-PLAGUE SERA.—Yersin, *Ann. de l'Inst. Pasteur* (1897), xi. 81. Lustig and Galeotti, *Deutsche med. Wchnschr.* (1897), No. 15. Montenegro, "Bubonic Plague," London, 1900. METHODS OF DIAGNOSIS.—Zettnow, *Ztschr. f. Hyg.* (1896), xxi. 165. Cairns, *Lancet* (1901), i. 1746.

MALTA FEVER.—ETIOLOGY.—Bruce, *Practitioner*, xxxix. 160; xl. 241; *Ann. de l'Inst. Pasteur* (1893), vii. 291. Bruce, Hughes, and Westcott, *Brit. Med. Journ.* (1887), ii. 58. Hughes, *Lancet* (1892), ii. 1265. MICROCOCCUS MELITENSIS.—Gordon, *Brit. Med. Journ.* (1899), i. 688. Ross, *Journ. Roy. Army Med. Corps* (1908), xiv. 618. RELATIONS TO THE DISEASE.—Hughes, *Ann. de l'Inst. Pasteur* (1893), vii. 628. EPIDEMIOLOGY.—Wright and Smith, *Brit. Med. Journ.* (1897), i. 656. Welch, *ibid.* (1897), i. 1512. Eyre, *Lancet* (1908), i. 1677. PATHOGENIC PROPERTIES.—Durham, *Journ. Path. and Bacteriol.* (1898), v. 377. Bruce, in "Davidson's Hygiene and Diseases of Warmer Climates," Edinburgh and London, 1893, p. 265. Eyre, in Kolle and Wassermann's *Handbuch d. Pathog. Mikroorganis.*, Ergänzungsband, 1906. Conor, *Centralbl. f. Bakteriol.* (Ref.), Abth. I. (1911), xlviii. 392. Eyre, *Proc. Roy. Soc. Edin.* (1909), xxix. 537. MODE OF SPREAD.—Horrocks, *Proc. Roy. Soc. London*, Series B (1905), lxxvi. 510. "Reports of the Commission on Mediterranean Fever," 1904–1907 (reprinted in *Journ. Roy. Army Med. Corps*). Dubois, *Centralbl. f. Bakteriol.* (Ref.) (1911), xlix. 704. Sergent, Gillot, and Lemaire, *Ann. de l'Inst. Pasteur* (1908), xxii. 209. METHODS OF DIAGNOSIS.—Wright and Semple, *Brit. Med. Journ.* (1897), i. 1214. Wright and Smith, *Lancet* (1897), i. 656. Sicre, *Ann. de l'Inst. Pasteur* (1908), xxii. 616. Bassett-Smith, *Journ. Hyg.* (1912), xii. 497.

CHAPTER XX.—DISEASES DUE TO SPIROCHÆTES.

RELAPSING FEVERS.—SPIRILLUM OF RELAPSING FEVER.—Obermeier, *Centralbl. f. d. med. Wissensch.* (1873), 145; and *Berl. klin. Wchnschr.* (1873), No. 35. Shellack, *Arb. a. d. k. Gsndhtsamte.* xxx. 351. CHARACTERS OF THE SPIROCHÆTE.—Norris, Pappenheimer, Flournoy, *Journ. Infect. Dis.* (1906), iii. 266. Zettnow, *Ztschr. f. Hyg.* (1906), lii. 485; *Deutsche med. Wchnschr.* (1906), 376. Fantham and Porter, *Proc. Roy. Soc.*, B (1909), lxxxi. RELATIONS TO THE DISEASE.—Münch, *Centralbl. f. d. med. Wissensch.*, 1876. Moczutkowsky, *Deutsches Arch. f. klin. Med.* (1879), xxiv. 192. Lubimoff, *Virchow's Archiv* (1884), xcviii. 160. MODE OF TRANSMISSION.—Tictin, *Centralbl. f. Bakteriol.* (1897), xxi. 179. Karlinski, *ibid.* (Orig.) (1902), xxi. 566. Manteufel, *Arb. a. d. k. Gsndhtsamte.* xxix. 337. Mackie, *Brit. Med. Journ.* (1907), ii. 1706. Fehrmann, *Centralbl. f. Bakteriol.* (Ref.), Abth. I. (1911), xlix. 361. IMMUNITY.—Koch, *Deutsche med. Wchnschr.* (1879), 327. Vandyke Carter, *Med.-Chir. Trans.*, London (1880), 78. Metchnikoff, *Virchow's Archiv*, cix. 176. Soudakewitch, *Ann. de l'Inst. Pasteur* (1891), v. 545. Lamb, *Scient. Mem. Med. Off. India* (1901), pt. xii. 77. Sawtschenko and Melkich, *Ann. de l'Inst. Pasteur* (1901), xv. 497. Gabritschewsky, *Ztschr. f. klin. Med.* (1905), Bd. 56. Novy and Knapp, *Journ. Infect. Dis.* (1906), iii. 291. Rabinowitsch, *Virchow's Archiv*, cxcix. 346. VARIETIES.—Novy, *Journ. Amer. Med. Assoc.* xlvii. 215. Mackie, *Lancet* (1907), ii. 832; *New York Med. Journ.* Aug. 22, 1908. Strong, *Philippine Journ. Med. Sc.* iv. 187. Sergent and Foley, *Ann. de l'Inst. Pasteur* (1910), xxiv. 337. Balfour, *Brit. Med. Journ.* (1911), i. 752; *Reps. Wellcome Laboratories* (1911), iv. 67. CULTIVATION.—Noguchi, *Journ. Exper. Med.* (1912), xvi. 194. Plotz, *ibid.* (1917), xxvi. 37.

AFRICAN TICK FEVER.—Ross and Milne, *Brit. Med. Journ.* (1904), ii.

1453. Dutton and Todd, *Thompson-Yates Laboratory Rep.* (1905), vi. pt. ii. Koch, *Deutsche med. Wchnschr.* (1905), 1865; *Berl. klin. Wchnschr.* (1906), No. 7, p. 185. Hodges and Ross, *Brit. Med. Journ.* (1905), i. 713. Breuil and Kinghorn, *ibid.* i. 668. Breuil, *Lancet* (1906), i. 1806. Levaditi, *Compt. Acad. Sc.* (1906), tome 142, 1099. Leishman, *Journ. R.A.M.C.* (1909), xii. 123; *Lancet* (1910), i. 1. Levaditi and Manouélian, *Ann. de l'Inst. Pasteur* (1907), xxi. 205. Hindle, *Parasitology* (1911), iv. 133, 183.

SYPHILIS.—GENERAL.—"Selected Essays on Syphilis and Smallpox," *New Sydenham Soc.*, 1906. Schaudinn and Hoffmann, *Berl. klin. Wchnschr.* (1905), Nos. 22, 23. Schaudinn, *Deutsche med. Wchnschr.* (1905), No. 22. Hoffmann, *Berl. klin. Wchnschr.* (1905), No. 46. Levaditi, *La Semaine méd.* (1905), 247; *Ann. de l'Inst. Pasteur* (1906), xx. 41. Hoffmann, "Die Ätiologie der Syphilis," Berlin, 1906. CULTURAL REACTIONS. — Schaudinn and Hoffmann, *Arb. a. d. k. Gsndhtsamte.* (1905), Bd. 22; *Deutsche med. Wchnschr.* (1905), No. 18. Herxheimer, *München. med. Wchnschr.* (1905), 1857. Levaditi and M'Intosh, *Ann. de l'Inst. Pasteur* (1907), xxi. 784. Mühlens, *Klin. Jahrb.* (1910), xxiii. 339. Hoffmann, *Ztschr. f. Hyg.* (1911), lxviii. 27; *Deutsche med. Wchnschr.* (1911), 1546. Noguchi, *Journ. Exper. Med.* (1911), xiv. 99; (1912), xv. 90; (1912), xvi. 199. TRANSMISSION OF THE DISEASE.—Metchnikoff and Roux, *Ann. de l'Inst. Pasteur*, xvii.–xix. Lassar, *Berl. klin. Wchnschr.* (1903), 1189. Neisser, *Deutsche med. Wchnschr.* (1904), 1369, 1431. Levaditi and Yamanouchi, *Ann. de l'Inst. Pasteur* (1908), xxii. 763. Neisser, "Die experimentelle Syphilisforschung," Berlin, 1906. Uhlenhuth and Mulzer, *Berl. klin. Wchnschr.* (1910), No. 25; (1911), No. 2. *Arbeit. a. d. kaiserl. Gsndhtsamte.* (1913), xliv. 307; *Centralbl. f. Bakteriol.*, Abth. I. (Ref.) (1913), lvii. Suppl. 158*. Nichols, *Journ. Exper. Med.* (1914), xix. 362. Wile, *ibid.* (1916), xxiii. 199. IMMUNITY. —Zinsser and Hopkins, *Journ. Exper. Med.* (1916), xxiii. 323. LUETIN REACTION.—Noguchi, *Journ. Amer. Med. Assoc.* (1912), lviii. 1163. EXPERIMENTAL THERAPY.—Ehrlich and Hata, "Die experimentelle Chemotherapie der Spirillosen," Berlin, 1910.

SERUM DIAGNOSIS.—Wassermann, Neisser, and Bruck, *Deutsche med. Wchnschr.* (1906), 745. Wassermann and Plaut, *ibid.* 1769. Wassermann, *Wien. klin. Wchnschr.* (1907), 745. Marie and Levaditi, *Ann. de l'Inst. Pasteur* (1907), xxi. 138; *Compt. rend. Soc. de biol.* (1907), lxii. 872. Porges and Meier, *Berl. klin. Wchnschr.* (1907), 1655, and (1908), 731. Sachs and Altmann, *ibid.* (1908), 494, 699. Sachs and Rondoni, *Ztschr. f. Immunitätsf.* i. 132. M'Kenzie, *Journ. Path. and Bacteriol.* (1909), xiii. 311. Browning, Cruickshank, and M'Kenzie, *ibid.* (1910), xiv. 484. Plaut, "Wassermann's Serodiagnostik der Syphilis in ihrer Anwendung auf die Psychiatrie," Jena, 1909. Landsteiner, *Centralbl. f. Bakteriol. u. Parasitenk.* (Ref.) (1908), xli. 785. Stern, *Ztschr. f. Immunitätsf.* i. 422. Noguchi, *Compt. rend. Soc. de biol.* (1909), lxvi. No. 11. See also discussion in *Brit. Med. Journ.* (1910), ii. Plaut, "Die Wassermannsche Reaction," Jena, 1909. Sachs und Altmann, in "Kolle and Wassermann's Handbuch der pathogenen Mikroorganismen," Ergänzungsband (1909), ii. Bruck, "Die Serodiagnose der Syphilis," Berlin, 1910. Levaditi et Roche, "La Syphilis," Paris, 1910. Noguchi, "Serum Diagnosis of Syphilis," Philadelphia, 1910. Boas, "Die Wassermannsche Reaction," Berlin, 1911. Browning and M'Kenzie, "Recent Methods in the Diagnosis and Treatment of Syphilis," London, 1911.

FRAMBŒSIA OR YAWS.—Castellani, *Brit. Med. Journ.* (1905), ii. 282, 1280, 1330 ; *Journ. Hyg.* (1907), 558. Neisser, Baermann, and Halberstädter, *München. med. Wchnschr.* (1906), 1337. Halberstädter, *Arb. a. d. k. Gsndhtsamte.* (1907), xxvi. 48. Levaditi and Nattan-Larrier, *Ann. de l'Inst. Pasteur* (1908), xxii. 260. Shennan, *Journ. Path. and Bacteriol.* (1908), xii. 426. Ashburn and Craig, *Philippine Journ. Med. Sc.* (1907), li. 441. Shüffner, *München. med. Wchnschr.* (1907), 1364. Nichols, *Journ. Exper. Med.* (1910), xii. 616 ; (1911), xiv. 196. Alston, *Brit. Med. Journ.* (1911), i. 360, 618. Keyser, *Bullet. de l'Inst. Pasteur* (1911), ix. 800.

SPIROCHÆTAL JAUNDICE.—Inada and others, *Journ. Exper. Med.* (1916), xxiii. 377, and (1917), xxvi. 341. Ito, Tetsuta, and Matsuzaki *ibid.* (1916), xxiii. 557. Noguchi, *ibid.* (1917), xxv. 755. Various other papers in same Journal, 1916–17. Stokes and Ryle, *Brit. Med. Journ.* (1916), ii. 413 ; Stokes, Ryle, and Tytler, *Lancet* (1917), i. 142. Martin and Pettit, *Compt. rend. Soc. de biol.* (1917), lxxx. 10.

RAT-BITE FEVER.—Futaki and others, *Journ. Exper. Med.* (1916), xxiii. 249, and (1917), xxv. 45. Ishiwara and others, *ibid.* (1917), xxv. Kamero and others, *ibid.* (1917), xxvi. 325. Scottmüller, *Dermat. Wchnschr.* (1914), lviii. Suppl. 77. Blake, *Journ. Exper. Med.* (1916), xxiii. 39. Douglas, Colebrook, and Fleming, *Lancet* (1918), i. p. 253.

CHAPTER XXI.—PATHOGENIC FUNGI.

GENERAL.—De Bary, "Comparative Morphology and Biology of the Fungi, Mycetozoa, and Bacteria," transl. by Garnsey and Balfour, Oxford, 1887. Marshall, "Microbiology," London, 1912. Strasburger and others, "Text-Book of Botany," London, 1912.

MICROSPORA, TRICHOPHYTA, ACHORIA.—Sabouraud, "Les Teignes," Paris, 1910. Plaut, in Kolle and Wassermann, "Handbuch der pathogenen Mikroorganismen," 2nd edition, 1912, Bd. v. FitzGerald, *Journ. Path. and Bacteriol.* (1908), xii. 232. Strickler, *Journ. Amer. Med. Assoc.* lxv. 225.

THRUSH.—Plaut, in Kolle and Wassermann, "Handbuch der pathogenen Mikroorganismen," 2nd edition (1912), v. 42.

ASPERGILLOSIS.—Virchow, *Virchow's Archiv* (1856), ix. 557. Saxer, "Pneumonomykosis Aspergillina," Jena, 1900. Axenfeld, "Bacteriology of the Eye," translated by M'Nab, London, 1908.

SPOROTRICHOSIS.—Gougerot, in Kolle and Wassermann, "Handbuch der pathogenen Mikroorganismen," Jena, 1912, 2nd edition, v. 211. Walker and Ritchie, *Brit. Med. Journ.* (1911), ii. 1. Schenk, *Johns Hopkins Hospital Bull.* (1898), ix. 286. Page, Frothingham, and Paige, *Journ. of Medical Research* (1910), xxviii. 157.

BLASTOMYCOSIS.—Ricketts, *Journ. Med. Res.* (1901), vi. 373. Rixford and Gilchrist, *Johns Hopkins Hosp. Rep.* (1896), i. 209. Wernicke, *Centralbl. f. Bakteriol. u. Parasitenk.* (1892), xii. 859. Buschke, "Die Blastomykose," Stuttgart, 1902. Busse, *Virchow's Archiv* (1896), cxliv. 360. Hektoen, *Journ. Amer. Med. Assoc.* (1907), xlix. 328. Evans, *Journ. Inf. Dis.* (1909), vi. 523. Irons and Graham, *ibid.* (1906), iii. 666.

MICROSPORON FURFUR.—Plaut, in Kolle and Wassermann, "Handbuch der pathogenen Mikroorganismen," Jena, 1912, 2nd edition, Bd. v.

CHAPTER XXII.—IMMUNITY.

GENERAL. — "Microparasites in Disease," *New Syd. Soc.* 1886. Ransome, "On Immunity to Disease," London, 1896. Discussion on Immunity, Path. Soc. London, *Brit. Med. Journ.* (1892), i. 373. Ritchie, *Journ. of Hyg.* (1902), ii. 215, 251, 452 (with full references). "General Pathology of Infection," in Clifford Allbutt's "System of Medicine," 2nd ed. 1906, vol. ii. pt. i. p. 1.

The following works dealing with the subject of Immunity have been published within recent years: Metchnikoff, "Immunity in Infective Diseases" (Engl. Transl.), Cambridge, 1905; Ehrlich, "Studies in Immunity" (Engl. Transl.), 2nd ed., New York, 1909; Bordet, "Studies in Immunity," New York, 1909; Kraus and Levaditi, "Handbuch der Technik und Methodik der Immunitätsforschung," Jena, 1908; Wright, "Studies on Immunisation," London, 1909. D'Este Emery, "Immunity and Specific Therapy," London, 1909; Muir, "Studies on Immunity," London, 1909; Wolff-Eisner, "Klinische Immunitätslehre und Serodiagnostik," Jena, 1910. The most important papers dealing with current work on the subject are published in the *Zeitschrift für Immunitätsforschung.*

ACTIVE IMMUNITY.—BY LIVING CULTURES.—Duguid and Sanderson, *Journ. Roy. Agric. Soc.* (1880), 267. Greenfield, *ibid.* (1880), 573; *Proc. Roy. Soc. London*, June 1880. Toussaint, *Compt. rend. Acad. d. sc.* xci. 135. Klein, *ibid.* (1893), i. 632, 639, 651. BY DEAD CULTURES.—Calmette, *Ann. de l'Inst. Pasteur*, viii. 275; xi. 95. Fraser, *Proc. Roy. Soc. Edin.* xx. 448. BY FEEDING.—Ehrlich, *Deutsche med. Wchnschr.* (1891), 976, 1218.

PASSIVE IMMUNITY.—ACTION OF SERUM OF HIGHLY IMMUNISED ANIMALS.—Charrin and Roger, *Compt. rend. Soc. de biol.* (1887), 667. SPECIFICITY OF ANTISUBSTANCES.—Wassermann, *Berl. klin. Wchnschr.* (1898), 1209. Pfeiffer and Marx, *Ztschr. f. Hyg.* (1898), xxvii. 272.

ANTITOXIC SERUM.—Metchnikoff, Roux, and Taurelli-Salimbeni, *Ann. de l'Inst. Pasteur*, x. 257. Cartwright Wood, *Lancet* (1896), i. 980; ii. 1145. Sidney Martin, "Serum Treatment of Diphtheria," *Lancet* (1896), ii. 1059. Salomonsen and Madsen, *Ann. de l'Inst. Pasteur* (1897), xi. 315; xii. 763. Roux and Borrell, *ibid.* xii. 225. Meade Bolton, *Journ. Exper. Med.* (1896), i. 543. Weigert, in Lubarsch and Ostertag, "Ergebnisse der allgemeinen Pathologie" (1897), iv. Jahrg. (Wiesbaden, 1899). DEVELOPMENT OF TOXIN.—Burdon Sanderson, "Croonian Lectures," *Brit. Med. Journ.* (1891), ii. 983, 1033, 1083, 1135. Hueppe, *Berl. klin. Wchnschr.* (1892), xxix. 409. STANDARDISING THE SERUM.—Ehrlich, "Die Wertbemessung des Diphtherieheilserums," Jena, 1897. SERA OF ANIMALS IMMUNISED AGAINST VEGETABLE AND ANIMAL POISONS.—Calmette, *Ann. de l'Inst. Pasteur* (1894), viii. 275; xi. 94. Fraser, *Proc. Roy. Soc. Edin.* xx. 448; *Brit. Med. Journ.* (1895), i. 1909; ii. 415, 416; (1896), i. 957; (1896), ii. 910; (1897), ii. 125, 595. Calmette, *Ann. de l'Inst. Pasteur* (1892), vi. 160, 604; ix. 225; x. 675; xi. 214; xii. 343. NATURE OF ANTITOXIC ACTION.—Buchner, *München. med. Wchnschr.* (1893), 449, 480. Wassermann and Takaki, *Berl. klin. Wchnschr.* (1898), xxxv. 4. Blumenthal, *Deutsche med. Wchnschr.* (1898), xxiv. 185. C. J. Martin, *Journ. Physiol.* xx. 364; *Proc. Roy. Soc. London*, lxiv. 88. C. J.

Martin and Cherry, *ibid.* lxiii. 428. Gautier, "Les Toxines microbiennes et animales," Paris, 1896. Dönitz, *Deutsche med. Wchnschr.* (1897), xxiii. 428. Bordet, *Ann. de l'Inst. Pasteur*, xvii. 161.

ANTIBACTERIAL SERUM.—R. Pfeiffer, *Ztschr. f. Hyg.* (1894), xviii. 1; (1895), xx. 198. Pfeiffer and Kolle, *ibid.* (1896), xxi. 203. Bordet, *Ann. de l'Inst. Pasteur* (1897), xi. 177. Marmorek, *Ann. de l'Inst. Pasteur* (1895), ix. 593. Fodor, *Deutsche med. Wchnschr.* xiii. 745.

PROPERTIES OF ANTIBACTERIAL SERUM.—Bordet, *Ann. de l'Inst. Pasteur* (1895), ix. 462; (1897), 177; xii. 688. BACTERICIDAL AND LYSOGENIC ACTION.—Grüber and Durham, *München. med. Wchnschr.* (1896), March. Durham, *Journ. Path. and Bacteriol.* (1897), iv. 13. Bordet, *Ann. de l'Inst. Pasteur*, xv. 303; xviii. 593. HÆMOLYTIC AND OTHER SERA.—Ehrlich and Morgenroth, *Berl. klin. Wchnschr.* (1898), xxxvi. 6, 481; (1900), xxvii. 453, 681; (1901), xxxviii. 251, 569, 598. Morgenroth, *Centralbl. f. Bakteriol.* (1899), xxvi. 349. Bordet, *Ann. de l'Inst. Pasteur*, xiv. 257.

OPSONINS.—Denys and Leclef, "La cellule" (1895), 177. Savtschenko, *Ann. de l'Inst. Pasteur* (1902), xvi. 106. Wright and Douglas, *Proc. Roy. Soc. London*, lxxii. 357; lxxiii. 128; lxxiv. 147. Wright and Reid, *ibid.* lxxvii. 211. Bulloch and Atkin, *ibid.* lxxiv. 379. Dean, *ibid.* lxxvi. 506; *Brit. Med. Journ.* (1907), ii. 1409. Discussion in *Centralbl. f. Bakteriol. u. Parasitenk.* (Referate) (1909), xliv. Supplement 14*. Bulloch and Western, *Proc. Roy. Soc. London*, lxxvii. 531. Neufeld and Rimpau, *Deutsche med. Wchnschr.* (1904), 1458. Neufeld, *Berl. klin. Wchnschr.* (1908), No. 21; *Med. Klinik.* (1908), No. 19. Hektoen and Ruediger, *Journ. Infect. Diseases* (1905), ii. 128. Hektoen, *ibid.* (1908), v. 259; (1909), vi. 78. Leishman, *Trans. Path. Soc. Lond.*, 1905. Muir and Martin, *Brit. Med. Journ.* (1906), ii.; *Proc. Roy. Soc. London*, B., lxxix. 187. Fornet and Porter, *Centralbl. f. Bakteriol. u. Parasitenk.* (Orig.) (1908), xlviii. 461.

AGGLUTINATION.—Nicolle, *Ann. de l'Inst. Pasteur*, xii. 161. Salimbeni, *ibid.* xi. 277. Bordet, *ibid.* xii. 688; xiii. 225, 273. Joos, *Ztschr. f. Hyg.* (1901), xxxvi. 422; (1902), xl. 203; *Centralbl. f. Bakteriol.* (Orig.) (1902–1903), xxxiii. 762. Eisenberg and Volk, *Ztschr. f. Hyg.* xl. 155. Dreyer and Jex-Blake, *Journ. Path. and Bacteriol.* (1906), xi. 1. Volk in Kraus and Levaditi's "Handbuch" (1909), Bd. ii. S. 623.

PRECIPITINS.—Welsh and Chapman, *Proc. Roy. Soc. London*, B. lxxix. (1907), 465; *Journ. Path. and Bacteriol.* (1909), xiii. 206. Kraus, *Wien. klin. Wchnschr.* (1907), No. 32. Uhlenhuth and Weidanz, in Kraus and Levaditi's "Handbuch" (1909), ii. 721. V. Eisler, *ibid.* 721. Nuttall, "Blood Immunity and Blood Relationship," Cambridge, 1904.

ACQUIRED IMMUNITY.—EHRLICH'S SIDE-CHAIN THEORY.—Ransom, *Deutsche med. Wchnschr.* (1898), xxiv. 117. Ehrlich, *Deutsche med. Wchnschr.* (1898), xxiv. 597; Croonian Lecture, *Proc. Roy. Soc. London* (1900), lxvi. 424; Nothnagel's "Specielle Pathologie und Therapie" (1901), Bd. viii. Schlussbetrachtungen. Bulloch, *Trans. Jenner Inst.*, 2nd ser. p. 46. THEORY OF PHAGOCYTOSIS.—Metchnikoff, *Virchow's Archiv*, xcvi. 177; xcvii. 502; (1887), cvii. 209; cix. 176; *Ann. de l'Inst. Pasteur* (1889), iii. 289; (1890), iv. 65, 193; (1891), v. 465; (1892), vi. 289; (1899), xiii. 737; (1890), xiv. 369; (1891), xv. 865. Savtschenko, *ibid.* xvi. 106.

NATURAL IMMUNITY.—Klemperer, *Arch. f. exper. Path. u. Pharmakol.* xxxi. 356. VARIATIONS IN NATURAL BACTERICIDAL POWERS.—

Metchnikoff, *Ann. de l'Inst. Pasteur*, vii. 403; vii. 562; (1894), viii. 257, 529; (1895), ix. 433. Ehrlich, *Deutsche med. Wchnschr.* (1901), xxvii. 866, 888, 913. Gengou, *Ann. de l'Inst. Pasteur*, xv. 232. Gruber and Futaki, *Centralbl. f. Bakteriol.*, Abth. I. (Ref.) (1906), xxxviii. Beiheft, S. 11. Neisser and Wechsberg, *München. med. Wchnschr.* (1901), No. 13. Von Dungern, *ibid.* (1899), 1288; (1900), 667, 963.

ANAPHYLAXIS.—Richet, *Compt. rend. Soc. de biol.*, 1903–1905; *Ann. de l'Inst. Pasteur* (1907), xxi. 497; (1908), xxii. 465. Arthus, *Compt. rend. Soc. de biol.* (1903), lv. 817. Arthus and Breton, *ibid.* lv. 1478. Th. Smith, Discussion on "Hypersensibility," in *Journ. Amer. Med. Assoc.* (1906), xlvii. 1010. Rosenau and Anderson, *Hyg. Lab. Bull.*, Washington, Nos. 29, 39, 45; *Journ. Infect. Diseases* (1907), vol. iv. 1. Otto, in v. Leuthold-Gedenkschrift, Bd. i.; art. "Anaphylaxie," in Kolle-Wassermann's "Handbuch," Ergänz.-Bd. ii. Hft. 2. Gay and Southard, various papers in *Journ. Med. Research* (1907), xvi. *et seq.* Doerr, art. "Anaphylaxie," in Kraus-Levaditi's "Handbuch." Various papers by Besredka in *Ann. de l'Inst. Pasteur*, 1907, *et seq.*, and by Biedl and Kraus, Friedberger, Doerr, and Russ, in *Ztschr. f. Immunitätsf.* Bd. ii. *et seq.* Bail, *ibid.* (1909), iv. 470. V. Pirquet and Schick, "Die Serumkrankheit," Wien, 1907. Currie, *Journ. Hyg.* (1907), vii. 35, 61. Goodall, *ibid.* 607. Scott, *Journ. Path. and Bacteriol.* (1909), xiv. 147 and (1910) xv. 31. Auer and Lewis, *Journ. Amer. Med. Assoc.* (1909), liii. 458. Friedberger, *Fortschr. d. Dtsch. Klin.* (1911), ii. 619. *Trans. XVII. Internat. Congr. of Med.* (1913), sect. iv. pt. ii. 1. Richet, "L'Anaphylaxie," Paris, 1912.

APPENDIX A.—SMALLPOX AND VACCINATION.

JENNERIAN VACCINATION.—Jenner, "An Inquiry into the Causes and Effects of the Variola Vaccinæ," London, 1798. Creighton, art. "Vaccination" in *Ency. Brit.*, 9th ed. Crookshank, "Bacteriology and Infective Diseases." M'Vail, "Vaccination Vindicated." RELATIONSHIP OF SMALLPOX TO COWPOX.—Chauveau, Viennois et Mairet, "Vaccine et variole, nouvelle étude expérimentale sur la question de l'identité de ces deux affections," Paris, 1865. Klein, *Rep. Med. Off. Local Govt. Board* (1892–93), 391; (1893–94), 493. Copeman, *Brit. Med. Journ.* (1894), ii. 631; *Journ. Path. and Bacteriol.* (1894), ii. 407; art. in Clifford Allbutt's "System of Medicine" (1897), vol. ii. Camus, *Compt. rend. Soc. de biol.* (1917), lxxix. 1108.

THE VIRUS OF SMALLPOX AND VACCINIA.—L. Pfeiffer, "Die Protozoen als Krankheitserreger," Jena, 1891. Ruffer, *Brit. Med. Journ.* (1894), vol. i. Guarnieri, *Centralbl. f. Bakteriol. u. Parasitenk.* (1894), xvi. 299. Ewing, *Journ. Med. Research*, xiii. 233. Prowazek, *Arb. a. d. kaiserl. Gesundheitsamte*, xxii. 535. Wasielewski, *Ztschr. f. Hyg.* (1901), xxxviii. 212. Bonhoff, *Berl. klin. Wchnschr.* (1905), 1142. Carini, *Centralbl. f. Bakteriol. u. Parasitenk.* (Orig.) (1905), xxxix. 685. Noguchi, *Journ. Exper. Med.* (1915), xxi. 539.

NATURE OF VACCINATION.—Béclère, Chambon, and Ménard, *Ann. de l'Inst. Pasteur* (1896), x. 1; (1898), xii. 837. Copeman, "Vaccination," London, 1899. Calmette and Guérin, *Ann. de l'Inst. Pasteur* (1901), xv. 161. Prowazek, *Arb. a. d. kaiserl. Gesundheitsamte*, xxiii. 525.

Appendix B.—Hydrophobia.

Pathology of Hydrophobia.—Pasteur, *Compt. rend. Acad. d. sc.* (1881), xcii. 1259 ; (1882), xcv. 1187 ; (1884), xcviii. 457 ; (1886), ciii. 777. Schaffer, *Ann. de l'Inst. Pasteur* (1889), iii. 644. Fleming, *Trans. 7th Internat. Cong. Hyg. and Demog.* iii. 16. Nocard and Roux, *Ann. de l'Inst. Pasteur* (1888), ii. 341. Babés, "Traité de la Rage," Paris, 1912.

Virus of Hydrophobia.—Helman, *Ann. de l'Inst. Pasteur* (1888), ii. 274 ; iii. 15. Bruschettini, *Centralbl. f. Bakteriol.* (1897), xx. 214 ; xxi. 203. Memmo, *ibid.* xx. 209 ; xxi. 657. Frantzius, *ibid.* xxiv. 971. Remlinger, *Ann. de l'Inst. Pasteur* (1903), xvii. 834 ; xviii. 150.

Negri Bodies.—Negri, *Ztschr. f. Hyg. u. Infectionskrankh.* xliii. 507 ; xliv. 519 ; lxiii. 421. Williams and Lowden, *Journ. Infect. Diseases*, iii. 452. Bertarelli, *Centralbl. f. Bakteriol.* xxvii. 556. D'Amato and Faggella, *Ztschr. f. Hyg.* (1910), lvi. 351. Frosch, in Kolle and Wassermann's "Handbuch der Pathogenen Mikroorganismen," Ergänzungsband, i. 626. Frothingham, *Am. Journ. Pub. Hyg.* (1908), xviii.

Prophylactic Treatment.—Pasteur, *Compt. rend. Acad. d. sc.* (1885), ci. 705 ; (1886), cii. 459, 835. Babés and Lepp, *Ann. de l'Inst. Pasteur* (1889), iii. 384. Remlinger, *ibid.* xix. 625. Harvey and M'Kendrick, *Sc. Mem. by Officers of Med. and Sanit. Depts., Govt. of India* (New Series), No. 30, Calcutta, 1907. Lamb and M'Kendrick, *ibid.* (1907), No. 36. Marie, *Ann. de l'Inst. Pasteur* (1905), xix. 1 ; (1908), xxii. 271. Högyes, Lyssa, in Nothnagel's "Spec. Path. u. Ther.," Vienna, 1897.

Methods of Diagnosis.—Roux, *Ann. de l'Inst. Pasteur*, i. 87.

Antirabic Serum.—Roux, *ibid.* ii. 479. Frantzius, *Centralbl. f. Bakteriol.* (1898), xxiii. 782. Semple, *Sc. Mem. by Off. of Med. and Sanit. Depts., Govt. of India*, No. 44, Calcutta, 1911.

Chlamydozoa.—For refs. see Minchin, "Protozoa," London, 1912.

Appendix C.—Malarial Fever.

Malarial Fever Parasite.—Laveran, *Bull. Acad. de méd.* (1880), ser. ii. vol. ix. 1346 ; "Du paludisme et de son hématozoaire," Paris, 1891. Marchiafava and Celli, *Fortschr. d. Med.*, 1883 and 1885 ; also in *Virchow's Festschrift.* Golgi, *Arch. pour le sc. med.*, 1886 and 1889 ; *Deutsche med. Wchnschr.* (1892), 663, 685, 707, 729. Councilman, *Fortschr. d. Med.* (1888), Nos. 12, 13. Osler, *Trans. Path. Soc. Philadelphia*, xii. xiii. Koch, *Berl. klin. Wchnschr.* (1899), 69. Ross, *Nature*, lxi. 522. Sexual and Asexual Cycle.—Golgi, *Fortschr. d. Med.* (1889), No. 3 ; *Ztschr. f. Hyg.* x. 136. Manson, *Brit. Med. Journ.* (1898), ii. 849. Ross, *Indian Med. Gaz.* xxxiii. 14, 133, 401, 448. Manson, *Lancet* (1900), i. 1417 ; ii. 151. Gray, *Brit. Med. Journ.* (1902), i. 1121. Daniel, *ibid.* (1901), i. 193. Lankester, *ibid.* (1902), i. 652. Minchin, "The Sporozoa," London, 1903. Ross and Thomson, *Ann. of Trop. Med.* (1910), iv. 267. Varieties of Parasite.—Sternberg, *New York Med. Rec.* xxix. No. 18. James, *ibid.* xxxiii. No. 10. Grassi and Feletti, *Riforma med.* (1890), ii. No. 50. Canalis, *Fortschr. d. Med.* (1890), Nos. 8, 9. Danilewsky, *Ann. de l'Inst. Pasteur*, xi. 758. "Parasites of Malarial Fevers," *New Syd. Soc.*, 1894 (Monographs by Marchiafava and Bignami, and by Mannaberg, with Bibliography). Manson, *Brit. Med. Journ.* (1894), i. 1252, 1307 ; *Lancet* (1895), ii. 402.

Nuttall, *Centralbl. f. Bakteriol. u. Parasitenk.* xxv. 877, 903; xxvi. 140; xxviii. 193, 218, 260, 328 (with full literature). Nuttall and Shipley, *Journ. of Hyg.* i. 45, 269, 451 (with literature). Ewing, *Journ. Exper. Med.* v. 429. Schaudinn, *Arbeit. a. d. kaiserl. Gesundheitsamte*, xix.; *Argutinsky Archiv mikroskop. Anat.* lix. 315; lxi. 331. Stephens and Christophers, "The Practical Study of Malarial and other Blood Parasites," 3rd ed. Liverpool, 1908. Thomson, *Ann. of Trop. Med.* (1911), v. 57. PATHOGENIC PROPERTIES.—Celli, "Malaria," trans. by Eyre, London, 1900; *Brit. Med. Journ.* (1901), i. 1030. Ewing, *Journ. Exper. Med.* vi. 119. METHODS OF EXAMINATION.—Leishman, *Brit. Med. Journ.* (1901), i. 635; ii. 757. Ross, "Mosquito Brigades and how to organise them," London, 1902. Ruge, in Kolle and Wassermann's "Handbuch d. path. Micro-organismen," Ergänzungsband, 1907 (full literature). Ross, *Lancet* (1903), i. 86. Bass and Johns, *Journ. Exper. Med.* (1912), xvi. 567. Thomson, M'Lellan, and Ross, *Ann. of Trop. Med.* (1912), vi. 449. King, *Journ. Exper. Med.* (1916), xxiii. 703.

BLACKWATER FEVER. — Stephens, art. "Blackwater Fever," in Allbutt's "System of Medicine," vol. ii. pt. ii. London, 1907. Laveran, "Traité du paludisme," 2nd ed., Paris, 1907. Christophers and Bentley, "Scientific Memoirs published by the Government of India," No. 35, Simla, 1908.

APPENDIX D.—AMŒBIC DYSENTERY.

ETIOLOGY.—Lösch, *Virchow's Archiv* (1875), lxv. 196. Cunningham, *Quart. Journ. Micr. Sc.*, N.S. (1881), xxi. 234. Kartulis, *Virchow's Archiv* (1886), cv. 118. Koch, *Arb. a. d. k. Gsndhtsamte.* (1883), iii. 65.

VARIETIES OF AMŒBÆ.—Kartulis, *Centralbl. f. Bakteriol.* (1887), ii. 745. Schaudinn, *Arb. a. d. k. Gsndhtsamte.* (1903), xix. 547. Kartulis, in Kolle and Wassermann's "Handbuch der path. Micro-organismen," Ergänzungsband, 1906. Craig, *Journ. Infect. Dis.* (1908), v. 324; "The Parasitic Amœbæ of Man," Philadelphia and London, 1911; *Journ. Med. Research* (1912), xxvi. 1. Hartmann, *Bull. de l'Inst. Pasteur* (1908), vi. 100; *Archiv f. Protistenk*, xviii. 207; xxiv. 163, 182. Werner, *Arch. f. Sciff. u. Tropenhyg.* xii. 11. Noc, *Ann. de l'Inst. Pasteur* (1909), xxiii. 177. Walker, *Journ. Med. Research* (1908), xvii. 379. Braun and Lühe, "Handbook of Practical Parasitology," New York, 1910. Elmassian, *Centralbl. f. Bakteriol.* (1909), Abth. I. (Orig.), lii. 335. CULTURAL REACTIONS.—Lesage, *Ann. de l'Inst. Pasteur* (1905), xix. 9. Musgrave and Clegg, "Amœbas, their Cultivation and Etiological Signification," Bureau of Government Laboratories, Manila, 1904. Wülker, *Centralbl. f. Bakteriol.*, Abth. I. (Ref.), 1911, l. 577. DISTRIBUTION OF AMŒBÆ.—Kartulis, *Centralbl. f. Bakteriol.* (Orig.) (1904), xxxvii. 527. PATHOGENIC PROPERTIES.—Kartulis, *Centralbl. f. Bakteriol.* (1891), ix. 365. Councilman and Lafleur, *Johns Hopkins Hosp. Rep.* (1891), ii. 395. Kruse and Pasquale, *Ztschr. f. Hyg.* (1894), xvi. 1. Viereck, *Bull. de l'Inst. Pasteur* (1907), v. 819. Greig and Wells, *Scient. Mems. Gov. of India*, No. 47, 1911. Quincke and Roos, *Berl. klin. Wchnschr.* (1893), 1089. Musgrave and Clegg, *Philipp. Journ. of Science* (1906), i. 936. Prowazek, *Arch. f. Protistenk.* (1911), xxii. 345; (1912), xxvi. 241. Wenyon, *Journ. Lond. Sch. Trop. Med.* (1912), ii. 27. Darling, *Arch. Intern. Med.* (1913), ii. 1. Walker and Sellards, *Philipp. Journ. of Science*, Sect. B. (1913), viii. 253. Phillips, "Amœbiasis and the Dysenteries," London, 1915.

APPENDIX E.—TRYPANOSOMIASIS, ETC.

GENERAL.—Laveran and Mesnil, "Trypanosomes et trypanosomiasis," Paris, Masson, 1904. Minchin, in Clifford Allbutt's "System of Medicine," 2nd ed. vol. ii. pt. ii. p. 9, London, Macmillan, 1907. Schaudinn, *Arbeit. a. d. kaiserl. Gesundheitsamte*, xx. 387. Mense, "Handbuch der Tropenkrankheiten," Leipzig, 1906, Barth. Novy and MacNeal, *Journ. Inf. Diseases*, ii. 256. Leishman, *Journ. Hyg.* iv. 434. Minchin and Thomson, *Proc. Roy. Soc. London*, B. (1909), lxxxii. 273. (Trypanosoma Cruzi) Chagas, *Memorias de Instituto Oswaldo Cruz*, i. (1909), 159; iii. (1911), 219. Vianna, *ibid.* iii. (1911), 276 (see *Bull. Sleep. Sickn. Bureau*, ii. (1910), 117; iv. (1912), 288, 341; *Bull. de l'Inst. Pasteur*, viii. (1910), 373. Hartmann, *Arch. f. Protistenk.* xx. (1910), 361. Chagas, *Bull. de la Soc. de path. exot.* iv. (1911), 467. Brumpt, *ibid.* v. (1912), 22. Minchin, "Protozoa," London, 1912. *Ann. de l'Inst. Pasteur* (1915), xxix. 537. Henry, *Journ. Path. Bacteriol.* xviii. (1913–14), 240.

SLEEPING SICKNESS.—Mott, *Reports of the Sleeping Sickness Commission of the Royal Society*, pt. vii. No. 15, London, Bale, Sons, & Dannielsson, 1906. Dutton and Todd, *Brit. Med. Journ.* (1903), i. 304. Dutton and Todd, *Thompson-Yates Lab. Rep.* v. pt. ii. i.; v. pt. ii. 97. Dutton, Todd, and Christy, *ibid.* vi. pt. i. p. 1. Manson and Daniels, *ibid.* (1903), i. 1249. *Idem*, *ibid.* (1903), ii. 1461. Low and Mott, *ibid.* (1904), i. 1000. Bettencourt, Kopke, Resende, and Mendes, *ibid.* (1903), i. 908. Castellani, *Reports of the Sleeping Sickness Commission of the Royal Society*, No. 1, i. 1, London, Harrison & Sons, 1903. Bruce and Nabarro, *ibid.* (1903), No. 1, ii. 11. Bruce, Nabarro, and Greig, *ibid.* (1903), No. 4, viii. 3. Greig and Gray, *ibid.* (1905), No. 6, ii. 3. Leishman, *Journ. Hyg.* iv. 434. Minchin, Gray, and Tulloch, *Reports of the Sleeping Sickness Commission of the Royal Society*, No. 8, xxi. 122. London, H.M. Stationery Office, 1907. Manson, *Brit. Med. Journ.* (1903), ii. 1249, 1461. See discussions at British Medical Association, *Brit. Med. Journ.* (1903), ii. 637; (1904), ii. 365. Thompson, *Thompson-Yates Lab. Rep.* vi. pt. ii. 1. Kleine, *Deutsche med. Wchnschr.* (1909), pp. 469, 924, 1257, 1956. Bruce, Hamerton, Bateman, and Mackie (Sleeping Sickness Commission of Royal Society, 1908–1909), *Proc. Roy. Soc. London*, B., lxxxi. 405; *ibid.* lxxxii. pp. 56, 63, 256, 368, 480, 485, 498. Bruce and others, *Proc. Roy. Soc. London*, B. (1910–11), lxxxiii. 345, 513; lxxxv. 423.

TR. RHODESIENSE.—Stephens and Fantham, *Proc. Roy. Soc. London*, B. (1910–11), lxxxiii. 28. *Journ. Path. and Bacteriol.* (1911–12), xvi. 407. Fantham and Thomson, *Proc. Roy. Soc. London*, B., lxxxiii. 206. Stannius and Yorke, *ibid.* lxxxiv. 156. Kinghorn and Yorke, *Ann. Trop. Med.* (1912), vi. 1. 269. Kinghorn, *Sleeping Sickness Bureau Bull.* (1911), iii. 391. Yorke, *Ann. Trop. Med.* iv. 351. Bevan, *Journ. Comp. Path. and Therap.* (1910), xxiii. 160; *Sleeping Sickness Bureau Bull.* (1911), iii. 21, 349; (1912), iv. 214. Sanderson, *Trans. Soc. Trop. Med.* (1912), 295. Mesnil and Ringenbach, *Compt. rend. Soc. de biol.* (1911), lxxi. 271; (1912), lxxii. 58. Laveran, *Compt. rend. Acad. d. sc.* (1911), cliii. 1112; (1912), cliv. 26; *Bull. de la Soc. de path. exot.* (1912), v. 101, 241. Bruce and others, numerous papers in *Proc. Roy. Soc. London*, B. (1912), lxxxv.; (1912–13), lxxxvi.; (1913–14), lxxxvii.; (1914–15), lxxxviii.

LEISHMANIA DONOVANI.—Leishman, *Brit. Med. Journ.* (1903), i. 1252.

Idem, in Clifford Allbutt's "System of Medicine," 2nd ed. vol. ii. pt. ii. 226, London, Macmillan, 1907. General Review of Leishmaniæ with bibliography, Leishman, *Quart. Journ. Med.* (1911–12), v. 109. *Idem*, Mense, "Handbuch der Tropenkrankheiten," iii. 591, Leipzig, Barth., 1906. Leishman and Statham, *Journ. of Roy. Army Med. Corps*, iv. 321. Donovan, *Brit. Med. Journ.* (1903), ii. 79. Rogers, *Quart. Journ. Micr. Soc.* xlviii. 367. *Idem*, *Brit. Med. Journ.* (1904), i. 1249; ii. 645. *Idem*, *Proc. Roy. Soc.* lxxvii. 284. Bentley, *Brit. Med. Journ.* (1904), ii. 653; *ibid.* (1905), i. 705. Christophers, *Scientif. Mem. by Officers of the Med. and Sanit. Dept. of the Govt. of India*, Nos. 8, 11, 15. Ross, *Brit. Med. Journ.* (1903), ii. 1401. See discussion at Brit. Med. Assoc., *Brit. Med. Journ.* (1904), ii. 642. Patton, *Sc. Mem. by Officers of Med. and Sanit. Depts. Govt. of India*, Calcutta, 1907, No. 27; *ibid.* 1912, No. 53. (Histoplasmosis) Darling, *Journ. Ex. Med.* (1909), xi. 515. Mackie, *Indian Journ. Med. Res.* (1915), ii. 934. Row, *ibid.* (1914), i. 617. Cornwall and others, *ibid.* (1916), iii. 698; (1917), iv. 105, 672. Laveran, *Ann. de l'Inst. Pasteur* (1914), xxviii. 823, 885; (1915), xxix. 1, 57.

Leishmania Infantum.—Nicolle, *Ann. de l'Inst. Pasteur* (1909), xxiii. 361, 441. See also references, *Bull. de l'Inst. Pasteur*, viii. 164, 680. Pianese, *Gazz. intern. di Medicin*, viii. 8.

Leishmania Tropica.—Wright, J. H., *Journ. Med. Research*, x. 472. Marzinowsky, *Ztschr. f. Hyg.* lviii. 327. Row, *Quart. Journ. Med. Sc.* liii. 747. Nicolle and Manceaux, *Ann. de l'Inst. Pasteur*, xxiv. 673. Thomson and Balfour, *Journ. Roy. Army Med. Corps* (1910), xiv. 1. Patton, *Scientif. Mem. by Officers of the Med. and Sanit. Dept. of the Govt. of India* (1910), No. 50.

Piroplasmosis.—See Minchin, *loc. cit. supra.* Koch, *Deutsche med. Wchnschr.* (1905), No. 47; *Ztschrft. f. Hyg. u. Infektionskrankh.* liv. i. Nuttall, *Journ. Hyg.* iv. 219. Nuttall and Graham-Smith, *ibid.* v. 237; vi. 586.

Appendix F.—Yellow Fever.

Sternberg, *Rep. Amer. Pub. Health Ass.* xv. 170. Sanarelli, *Ann. de l'Inst. Pasteur*, xi. 433, 673, 753; xii. 348. Davidson, art. in Clifford Allbutt's "System of Medicine," vol. ii. London, 1897. Sternberg, *Centralbl. f. Bakteriol. u. Parasitenk.* xxii. 145; xxiii. 769. Sanarelli, *ibid.* xxii. 668. Reed and Carroll, *Medical News*, April 1899. Reed, *Journ. of Hyg.* ii. 101 (with full references). Durham, *Thompson-Yates Laboratory Rep.* (1902), iv. pt. ii. 485. Gorgas, *Lancet*, 1902, Sept. 9; 1903, March 28. Marchoux, Salimbeni, and Simond, *Ann. de l'Inst. Pasteur*, xvii. 665; xx. 16, 104, 161. Bandi, *Ztschr. f. Hyg.* (1904), xlvi. 81. Otto and Neumann, *Ztschr. f. Hyg.* (1905), li. Heft 3. Reed, Carroll, Agramonte, Lazear, *Proc. Amer. Health Ass.*, 1900; *Journ. Amer. Med. Ass.*, Feb. 1901. Carroll, *New York Med. Journ.*, Feb. 1904; *Amer. Medicine* (1906), xi. 383. Thomas, *Brit. Med. Journ.* (1907), i. 138. Seidelin, *Yellow Fever Bureau Bull.*, vol. ii. No. 2, Oct. 1912; in this publication there will be found an excellent summary of recent literature.

Appendix G.—Epidemic Poliomyelitis.

Landsteiner and Popper, *Ztschr. f. Immunitätsforschung* (Orig.) (1902), ii. 377. "Epidemic Poliomyelitis," Report on New York Epidemic of

1907, New York, 1910. Flexner and others, *Journ. Amer. Med. Ass.* (1909), liii. 1639, 1913, 2095; (1910), liv. 45, 1140, 1780; lv. 662; (1911), lvi. 585, 1717, 1750; lvii. 1685; (1912), lviii. 109; lix. 273. Landsteiner and Levaditi, *Compt. rend. Soc. de biol.* lvii. 592, 787. Levaditi and Landsteiner, *ibid.* lviii. 3, 11, 417. Netter and Levaditi, *ibid.* lviii. 617, 855. Levaditi, *Presse méd.* (1910), 43. Jelliffe, *Journ. Amer. Med. Assoc.* (1911), lvi. 1868. Lentz and Huntemüller, *Ztschr. f. Hyg.* (1909), lxvi. 481. Kraus, *Ztschr. f. Immunitätsf.* (Orig.) (1911), ix. 117. Landsteiner, Levaditi, and Pastea, *Compt. rend. Acad. des Sciences* (1911), clii. 1701. Landsteiner, Levaditi, and Danulesco, *Compt. rend. Soc. de biol.* lxxi. 558, 651. Internat. Congress of Hyg. and Demography, *Journ. Amer. Med. Ass.* (1912), lix. 1311. Kling, Wernstedt, and Petterssen, *Ztschr. f. Immunitätsf.* (Orig.) (1912), xii. 316, 657. Römer, *Deutsche med. Wchnschr.* (1911), 1209, 1371; (1913), lx. 201, 362; (1916), lxvii. 279, 583. Flexner and Noguchi, *Journ. Exp. Med.* (1913), xviii. 461. Flexner, Clark, and Amoss, *ibid.* (1914), xix. 195; *ibid., idem*, 205; Amoss, *ibid., idem*, 212; Clark, Fraser, and Amoss, *ibid., idem*, 223; Flexner and Amoss, *ibid., idem*, 411; *ibid.* (1914), xx. 249; Flexner, Noguchi, and Amoss, *ibid.* (1915), xxi. 91; Flexner and Amoss, *ibid.* (1917), xxv. 499, 525; Amoss and Taylor, *ibid., idem*, 507; Amoss, *ibid., idem*, 545; Amoss and Chesney, *ibid., idem*, 581. (Streptococci) Rosenow and Towne, *Journ. Med. Res.* (1917), xxxvi. 175. Epidemic Encephalitis.—Kinnier Wilson, *Lancet* (1918), ii. 7. Netter, *ibid.* (1918), i. 76. Economo, *Wien. klin. Wchnschr.* (1917), xxx. 581. Von Wiesner, *ibid.* (1917), xxx. 933. Breinl, *Med. Journ. of Australia* (1918), i. 209, 229. Wernicke, *Lehrbuch der Gehronkrankheiten*, Kassel, 1881–83. Bull, *Journ. Exp. Med.* (1917), xxv. 557; Kolmer, Brown, and Freese, *ibid., idem*, 789.

Appendix H.—Phlebotomus Fever.

Doerr, *Berl. klin. Wchnschr.* (1908), 1847. Doerr, Franz, and Taussig, "Das Pappatacifieber," Leipzig, and Vienna, 1909. Birt, *Journ. Roy. Army Med. Corps* (1910), 142, 236. Manson, in Clifford Allbutt's "System of Medicine" (1907), ii. (2) 345. Ashburn and Craig, *Philippine Journ. Sc. Med.* ii. 93 (Ref. in *Bull. de l'Inst. Pasteur* (1907), v. 773). Leger and Seguimaud, *Bull. Soc. Path. Exot.* (1912), v. 210. Gabbi, *Ann. Trop. Med.* (1911–12), v. 135. (Life History of Phlebotomus Pappatasii) Marett, *Journ. Roy. Army Med. Corps* (1911), xvii. 13. Newstead, *ibid.* (1912), xviii. 613; xix. 28, 162.

Appendix J.—Typhus Fever.

Nicolle and others, *Ann. de l'Inst. Pasteur* (1910), xxiv. 243; (1911), xxv. 1, 97; (1912), xxvi. 250, 332. *Compt. Rend. Acad. d. sc.* clix. 661; clxi. 646; clxii. 525. *Bull. Soc. Path. Exot.* ix. 487; *Arch. de l'Inst. Past. Tunis*, ix. 127. Ricketts and Wilder, *Journ. Amer. Med. Ass.* (1910), liv. 463, 1304, 1373; (1910), lv. 309. "Collected Studies on Typhus," Treasury Dept., U.S. Public Health Service, *Hygienic Laboratory Bulletin*, No. 86, Oct. 1912, Washington Govt. Printing Office, 1912 (20 cents). Hayler and Prowazek, *Berl. klin. Wchnschr.* (1913), No. 44. Rocha-Lima, *ibid.* (1916), 567. Topfer and Schussler,

Deutsche med. Wchnschr. (1916), 1157. Plotz, *Presse méd.* (1914), 411; Plotz, Olitzky, and Baehr, *Journ. Inf. Dis.* (1915), xvii. 1. Olitzky, *ibid.* (1917), xx. 349. Dietrich (Weil-Felix reaction), *Deutsche med. Wchnschr.* (1916), 1570. Rocky Mountain Fever.—Wolbach, *Journ. Med. Research* (1916), xxxiv. 121; (1916–17), xxxv. 147; (1917–18), xxxvii. 499. Cumming, *Journ. Inf. Dis.* (1917), xxi. 509.

Appendix K.—Trench Fever.

Hunt and Rankin, *Lancet* (1915), ii. 1133. M'Nee and Renshaw, *Brit. Med. Journ.* (1916), i. 225. *Journ. R.A.M.C.*, xxvi. 490. Hurst, *Lancet* (1916), ii. 671. Grieveson, *Lancet* (1917), ii. 84. Davies and Wellden, *Lancet* (1917), i. 183. Strong, *Med. Bull. Amer. Red Cross Soc. in France* (1918), i. 376. Byam and others, see *Lancet* (1918), i. 743, 774; *Trans. Soc. Trop. Med. and Hyg.* (1918), xi. 237. "Trench Fever," *Report of Med. Research Commission, Amer. Red Cross*, Oxford, 1918.
